of those species are threatened with extinction as a result of a combination of decline in quantity and quality of habitat (Davis *et al.*, 2006). They differ greatly in morphology, size, and ecological adaptations. Some species like *C. canephora* and *Coffea liberica* Hiern are widely distributed from Guinea to Uganda. Other species display specific adaptations, e.g., *Coffea congensis* Froehner to seasonally flooded areas in the Zaire basin and *Coffea racemosa* Lour. to very dry areas in the coastal region of Mozambique. All species are diploid ($2n=2x=22$) and generally self-incompatible, except for *C. arabica*, which is tetraploid ($2n=4x=44$) and self-fertile (Charrier and Berthaud, 1985).

Molecular phylogeny of *Coffea* species has been established based on DNA sequence data. The internal transcribed spacer (ITS2) region of the nuclear ribosomal DNA (Lashermes *et al.*, 1997) as well as the chloroplast-DNA variation (Lashermes *et al.*, 1996; Cros *et al.*, 1998) were successfully used to infer phylogenetic relationships of *Coffea* species. No major difference between coffee and other plants was observed in the arrangement of the chloroplast genome and in the structure of the ITS2 region in nuclear rDNA. Furthermore, the results suggest a radial mode of speciation and a recent origin in Africa for the genus *Coffea*. Several major clades were identified, which present a strong geographical correspondence (i.e., Madagascar, East Africa, Central Africa, Central and West Africa). In addition, *Psilanthus* species did not differ from *Coffea* species, suggesting that the present division into two genera should be revised.

1.3 Speciation and Genome Features of *C. arabica*

The genome constitution and mode of speciation of *C. arabica* have been subjected to several investigations. Based on cytological observations and fertility of interspecific hybrids, *C. canephora* and *C. congensis* were suggested to have a common ancestor with *C. arabica* (Carvalho, 1952; Cramer, 1957). Furthermore, *C. congensis* can be considered as an ecotype of *C. canephora* in the light of the fertility of interspecific hybrids (Louarn, 1993) and the genetic diversity detected by molecular markers (Prakash *et al.*, 2005). These

phylogenetic assumptions were consolidated by a high homology found in the ITS2 region sequences of *C. arabica*, *C. canephora*, and *C. congensis* (Lashermes *et al.*, 1997). Regarding cpDNA that exhibited a maternal inheritance in coffee (Lashermes *et al.*, 1996), *C. arabica* appeared to be similar to two species, *Coffea eugenioides* Moore and *Coffea* sp. "Moloundou" (Cros *et al.*, 1998).

Restriction fragment length polymorphism (RFLP) markers in combination with genomic *in situ* hybridization (GISH) were used to investigate the origin of *C. arabica*. By comparing the RFLP patterns of potential diploid progenitor species with those of *C. arabica*, the source of the two sets of chromosomes, or genomes, combined in *C. arabica* was specified. The genome organization of *C. arabica* was confirmed by GISH using simultaneously labeled total genomic DNA from the two putative genome donor species as probes (Lashermes *et al.*, 1999). These results clearly suggested that *C. arabica* is an amphidiploid (i.e., C^aE^a genomes) resulting from the hybridization between *C. eugenioides* (E genome) and *C. canephora* (C genome) or ecotypes related to those diploid species (Figure 1). Results also indicated low divergence between the two constitutive genomes of *C. arabica* and those of its progenitor species, suggesting that the speciation of *C. arabica* took place very recently. Precise

Figure 1 Origin of the allotetraploid species *Coffea arabica* (C^aE^a genomes)

localization in Central Africa of the speciation process of *C. arabica* based on the present distribution of the coffee species appeared difficult since the constitution and extent of tropical forest varied considerably during the late quaternary period.

Furthermore, in spite of the close relationship among the two constitutive genomes, bivalents are observed in meiosis and *C. arabica* is considered to display a diploidlike meiotic behavior (Krug and Mendes, 1940). Investigations suggest that homologous chromosomes do not pair in *C. arabica*, not as a consequence of structural differentiation, but because of the functioning of pairing regulating factors (Lashermes *et al.*, 2000a).

The nuclear DNA content of several coffee species has been estimated by flow cytometry (Cros *et al.*, 1995). The DNA amount (2C values) varies between diploid coffee species from 0.95 to 1.8 pg (picogram). In comparison to other angiosperms (Bennett and Leitch, 1995), the genomes of coffee species appear to be of rather low size (i.e., 800 and 1300 Mb for *C. canephora* and *C. arabica*, respectively). These variations in DNA amount, other than variation due to ploidy level (e.g., *C. arabica*), are probably due almost entirely to variation in the copy number of repeated DNA sequences. Differences may correspond to genomic evolution correlated with an ecological adaptation process. Furthermore, reduced fertility of certain interspecific F₁ hybrids appears to be associated with significant differences in nuclear content of parental species (Barre *et al.*, 1998).

1.4 Traditional Breeding: Breeding Objectives, Tools, and Strategies

C. arabica is characterized by very low genetic diversity, which is attributable to its allotetraploid origin and evolution. It is believed that the agromorphological variation observed, which gave rise to so many named varieties during the 20th century, results from spontaneous mutations in a few major genes conditioning plant, fruit, and seed characters (Carvalho, 1988). The cultivars present, therefore, a homogeneous agronomic behavior characterized by a high susceptibility to many pests and diseases, and very low adaptability (Bertrand *et al.*, 1999). Spontaneous accessions collected in

the primary center of diversity as well as wild relative *Coffea* species constitute a valuable gene reservoir for breeding purposes.

Transfer of desirable genes in particular for disease resistance from diploid species like *C. canephora* and *C. liberica* into tetraploid Arabica cultivars without affecting quality traits has been the main objective of Arabica breeding (Carvalho, 1988; Van der Vossen, 2001). To date, *C. canephora* provides the main source of disease and pest resistance traits not found in *C. arabica*, including coffee leaf rust (*Hemileia vastatrix*), coffee berry disease (*Colletotrichum kahawae*) and root-knot nematode (*Meloidogyne* spp.). Likewise, other diploid species present considerable interests in this respect. For instance, *C. liberica* has been used as source of resistance to leaf rust (Srinivasan and Narasimhaswamy, 1975) while *C. racemosa* constitutes a promising source of resistance to the coffee leaf miner (CLM) (Guerreiro Filho *et al.*, 1999). Exploitation of such genetic resources has so far relied on conventional procedures in which a hybrid is produced between an outstanding variety and a donor genotype carrying the trait of interest, and the progeny is backcrossed to the recurrent parent. Undesirable genes from the donor parent are gradually eliminated by selection. In so doing, conventional coffee breeding methodology faces considerable difficulties. In particular, strong limitations are due to the long generation time of coffee tree (5 years), the high cost of field trial, and the lack of accuracy of current strategy. A minimum of 25 years after hybridization is required to restore the genetic background of the recipient cultivar and thereby ensure good quality of the improved variety.

Occurrence of spontaneous hybrids between *C. arabica* and diploid relative species such as *C. canephora* and *C. liberica* is reported from time to time, especially when these species grow in direct proximity (Mahé *et al.*, 2007). Those exceptional natural hybrids have been intensively used in coffee breeding programs as the main source of resistance to pests and diseases. In particular, the Timor Hybrid, a natural hybrid originating from an interspecific cross between *C. arabica* and *C. canephora* (Bettencourt, 1973; Lashermes *et al.*, 2000b) is being extensively used as the main source of resistance to pests and diseases, including coffee leaf rust (*H. vastatrix*), coffee berry disease (CBD) caused by *C. kahawae*, and

resistance to root-knot nematode (*Meloidogyne exigua*). Alternatively, genes from diploid coffee could be transferred into the *C. arabica* genome through the production of triploid ($2n=33$) or tetraploid ($2n=44$) interspecific hybrids (Herrera *et al.*, 2002a, b, 2004). Triploid hybrids are derived from a direct cross between the diploid progenitor and *C. arabica* while tetraploid hybrids are obtained by crossing both the species after chromosome duplication of the diploid coffee. The use of triploid hybrids is more difficult than tetraploid hybrids because of low fertility. Nevertheless, selection of high producing lines in early generations derived from triploid hybrids (i.e., first backcross to *C. arabica* or second generation by selfing) has been reported (Orozco Castillo, 1989).

The use of molecular techniques has opened up new possibilities for genetic analysis and provides new tools for efficient conservation and use of coffee genetic resources. For instance, a whole range of different DNA molecular marker techniques has been used to study the genetic diversity in *C. arabica*. The base populations of cultivated coffee appeared to derive from wild coffee collected in southwestern Ethiopia. In addition, spontaneous accessions collected in the primary center of diversity seemed to constitute a valuable gene reservoir. These results should increase interest in wild coffee for the purpose of broadening the genetic base of the cultivars. Moreover, heterosis has been reported in F_1 hybrids resulting from crosses between subspontaneous Ethiopian accessions and improved cultivars (Bertrand *et al.*, 2005). Furthermore, the recent development of molecular markers closely linked to resistance genes against *M. exigua* (Noir *et al.*, 2003) and leaf rust (Prakash *et al.*, 2004) opened up the possibility of molecular marker-assisted selection.

1.5 Toward the Identification and Characterization of Coffee Genes

The recent development of large coffee expressed sequence tag (EST) sequencing projects (Lin *et al.*, 2005; Viera *et al.*, 2006) as well as the development of coffee bacterial artificial chromosome (BAC) genomic libraries (Noir *et al.*, 2004; Leroy *et al.*, 2005) is leading to an enormous production

of information in the area of coffee genomics. To take advantage of these resources, a key issue is the development and use of methods to define gene functions at the molecular and organism level. The identification of specific genes involved in significant coffee biological processes is a prerequisite for interpretation of molecular information on the structure and organization of the coffee genome. Tools are, therefore, required that allow both forward and reverse genetics in coffee as well as the elucidation of gene function, regulation and interaction of genes.

The overall benefit of the application of genomics to coffee will be to increase the precision of genetic improvement and coffee growing practices by establishing refined correlation between molecular characters (i.e., genes, proteins, and metabolites) and important agricultural traits. With the advent of such knowledge, the development of improved cultivars in terms of quality and reduced economic and environmental costs can be achieved with an increased probability of success.

2. DEVELOPMENT OF TRANSGENIC COFFEE

Coffee genetic engineering emerged during the last decade as a potential tool with two objectives: (i) to elucidate the function, regulation, and interaction of agronomically interesting genes through functional genomics approach, and (ii) to serve as a tool to introduce desirable traits into commercial genotypes.

However, these objectives were available only after the establishment of protocols for *in vitro* regeneration through somatic embryogenesis for both the principal commercial species. Two types of somatic embryogenesis processes have been described using leaf sections as explants that enable efficient regeneration of plantlets from different tissues: (i) *direct somatic embryogenesis*: somatic embryos are obtained quickly (approximately 70 days) on only one medium with the production of limited callusing. This procedure is particularly suited to *C. canephora* and (ii) *indirect somatic embryogenesis* based on the use of two media: an induction medium for primary callogenesis, and a secondary regeneration medium to produce friable embryogenic callus regenerating several hundred

thousand somatic embryos per gram of callus on both *Coffea* sp. (Etienne, 2005).

2.1 Donor Gene

2.1.1 Gene source

The recent development of high throughput methods for analyzing the structure and function of genes represents a new paradigm with broad implications for agricultural production. With the complete sequencing of the first model organisms and the development of centers of excellence in genomics, the knowledge of genomes and their expression increases exponentially, inclusive for woody plants like coffee. During the last decade, important efforts were made in coffee to develop EST databases. The Brazilian government funded an ambitious Coffee Genome Program with the objective to establish a data bank of more than 200 000 ESTs, which could lead to the identification of more than 30 000 genes. Recently, a collaborative Nestlé-Cornell University team published an EST database of around 47 000 cDNA clones, corresponding to 13 175 unigenes (Lin *et al.*, 2005). In parallel, BAC libraries of both coffee species, *C. arabica* and *C. canephora*, were established (Noir *et al.*, 2004; Leroy *et al.*, 2005). Such maps are of central strategic importance for marker-assisted breeding, for straightforward positional cloning of agronomical important genes, and analysis of gene structure and function.

As a consequence of the recent efforts on coffee genomics, a lot of coffee gene candidates have been identified and some of them are currently under cloning. Among them, are pathogen resistance genes including *Mex-1* gene to *M. exigua* root-knot nematode (Noir *et al.*, 2003), *Sh-3* gene to race 3 of coffee leaf rust (*H. vastatrix*) (Prakash *et al.*, 2004), and *Ck-1* gene to CBD (*C. kahawae*) (Gichuru *et al.*, 2006) and others involved in physiological functions such as sucrose synthase (Leroy *et al.*, 2005), caffeine synthase (Ogita *et al.*, 2004; Satyanarayana *et al.*, 2005), seed's oil content (Simkin *et al.*, 2006), and osmotic stress response (Hinniger *et al.*, 2006). For the mentioned intrinsic genes and for the ones to be discovered, the availability of efficient genetic transformation procedures becomes necessary in order to validate

their function and to analyze their structure. On attendance, the majority of transformation events done until now in coffee correspond principally to *uidA* and/or *gfp* (green fluorescent protein) reporter genes inserted between T-DNA borders in pBIN or pCambia type binary backbone (see Table 1). Exceptions to the previous was done by Leroy *et al.* (2000), who achieved stable transfer of *cry1Ac* gene (from *Bacillus thuringiensis* (Bt) and encodes an endotoxin active against CLM *Perileuoptera coffeela*) and of *csr1-1* gene (conferring resistance to chlorsulfuron herbicide).

In addition, Ogita *et al.* (2003) and Kumar *et al.* (2004) reported the production of transformed plants with suppression of the expression of the genes that encode the enzymes theobromine synthase (*CaMXMT1*) and N-methyl transferase (*NMT*) respectively, both involved in caffeine biosynthesis. In particular, Ogita *et al.* (2003) achieved production of doubled stranded RNA interference (RNAi) method. RNAi sequences homologous to the *CaMXMT1* mRNA have given as a result that leaves of one-year-old transformed trees exhibited reduced theobromine and caffeine content (30–50% compared with the control).

2.1.2 Promoters

With few exceptions, the 35S promoter, derived from the cauliflower mosaic virus (CaMV), has been the most common component of transgenic constructs used with either direct or indirect *Agrobacterium*-mediated coffee transformation (see Table 1). Surprisingly, apart of van Bostel *et al.* (1995) and Rosillo *et al.* (2003) who tested different promoters controlling *uidA* gene and compared its expression in endosperm, somatic embryos, and leaf explants of *C. arabica*, none other research group has done this type of research in coffee. van Bostel *et al.* (1995) found that EF-1 α promoter (from *Arabidopsis thaliana* EF-1 α translation elongation factor p35S driven) revealed the most efficient *GUS* gene transient expression; however, the use of this promoter has been further restricted to this group (Leroy *et al.*, 2000; Perthuis *et al.*, 2005). Rosillo *et al.* (2003) compared the efficacy of transfer and expression of *GUS* gene driven by 35S with respect to two coffee promoters

Table 1 Summary of transformation studies in *Coffea* sp.^(a)

^(c) Unpublished results

(α -tubulin and α -arabacin); under their protocol conditions, all promoter constructs resulted in similar transient expression of *GUS* gene. It opens the possibility that pCaMV 35S could be replaced with a coffee promoter.

Not less important is the lack of studies about the characterization and specific localization of p35S-driven-*GUS* activity in transformed tissues of coffee. Sreenath and Naveen (2004) carried out a histochemical survey of p35S-*GUS* activity comparing various tissues in untransformed and transformed embryogenic calli and somatic embryos, and demonstrated that coffee possesses an endogenous *GUS* activity that is expressed at different levels in different tissues, but differs from introduced bacterial *GUS* activity in optimal pH requirement and sensitivity to methanol. Hatanaka *et al.* (1999) demonstrated that leaves and roots of p35S-*GUS* transformed plants exhibited a deep blue color in reaction with X-gluc, while nontransformed plantlets did not react with X-Gluc. Leroy *et al.* (2000) found that 50% of the embryogenic callus transformed with pEF-1 α -*GUS* driven promoter and growing on culture media containing a high dose of chlorsulfuron (80 $\mu\text{g l}^{-1}$) did not exhibit a blue staining. This work clearly demonstrated that increasing the selective marker concentration does not alleviate the problem of escapes and decreased the rate of transformation events. Therefore, this research team used *GUS* histochemical test as a secondary screening of whole plantlets. Recently, Alpizar *et al.* (2006a), found that distribution of p35S-*GUS* expression exhibits the same pattern of expression within the same root system but this pattern can be variable between root systems. In all situations, the strongest p35S-*GUS* expression was always observed in the root tip and in the central cylinder.

Ogita *et al.* (2004) demonstrated that epifluorescence of p35S-*gfp* gene was constitutively detected throughout the entire coffee somatic embryo. Similar results were reported in coffee by Canche-Moo *et al.* (2006) in somatic embryos and Alpizar *et al.* (2006b) in roots, using p35S-*DsRFP* and p35S-*gfp* genes, respectively. Satyanarayana *et al.* (2005) recently achieved cloning of the first promoter for the *NMT* gene involved in caffeine biosynthesis, which will be very useful in near future for studying the regulation of caffeine biosynthesis genes.

2.2 Methods Employed

2.2.1 Direct gene transfer

After the first report from Barton *et al.* (1991) of transformation of coffee embryos by electroporation using the *nptII* (neomycin phosphotransferase II) (kanamycin resistance) gene, this method remained unmentioned until the recent works of Fernandez-Da Silva and Menéndez-Yuffá (2003) (see Table 1) that described improved conditions to regenerate transformed *C. arabica* somatic embryos and plantlets expressing the *GUS* and *bar* genes (Figure 2e). Their experiments showed that the electroporation of somatic embryos at torpedo stage can be promising as a method for coffee transformation since they showed the best transient *GUS* expression and regeneration through secondary somatic embryogenesis. The expression of *gus* and *bar* genes was confirmed by polymerase chain reaction (PCR) reaction in the regenerated plants several months after the electroporation of the tissues (De Guglielmo and Menéndez-Yuffá, unpublished results).

Biolistic delivery method has been improved considerably since the first report of *GUS* transient expression in coffee using a powder driven gun by van Bostel *et al.* (1995). Rosillo *et al.* (2003) studied diverse interactions between osmotic preconditioning of *C. arabica* suspension cells and physical parameters using helium gun device. They determined that a short period of endosperm pretreatment with two nonmetabolized agents (mannitol and sorbitol) increased the number of cells expressing *GUS* gene without causing cell necrosis after bombardment. The authors discussed the advantage of using this type of osmotic agents instead of sucrose in order to reduce the turgor pressure of cells and increase cell survival by avoiding the leakage after the shock wave created during bombardment. Ribas *et al.* (2005a) described a protocol for transformation of embryogenic callus and somatic embryos of *C. canephora* using a helium gun, associated with subculturing onto medium containing mannitol before and after bombardment. Their protocol allowed 12.5% of transformed callus expressing *GUS*-positive reaction to histochemical assay.

De Guglielmo and Menéndez-Yuffá (unpublished results), using a pistol at low helium pressure evaluated the efficacy of this technique in

Figure 2 *A. tumefaciens*-mediated transformation of coffee tree. (a) Selective proliferation of cream colored transgenic embryogenic calli of *C. arabica* in the presence of 100 mg l^{-1} hygromycin. The nontransformed calli have turned brown. Transgenic calli were obtained from embryogenic calli co-cultivated with *Agrobacterium tumefaciens* carrying a binary plasmid with *hpt* gene driven by CaMV35S promoter. (b) Transgenic somatic embryos of *C. arabica* differentiated from transgenic calli selected in presence of 100 mg l^{-1} hygromycin. (c) Transgenic plant of *C. canephora* cv. C \times R derived from *A. tumefaciens*-mediated transformation and selected in presence of hygromycin. (d) Transgenic plantlet of *C. arabica* showing blue color indicating strong *gus* gene expression. (e) Coffee Catimor plantlet regenerated from somatic embryos electroporated with pCambia3201

transformation efficacy of torpedo and globular somatic embryos, embryogenic callus, and *in vitro* plant leaves of *C. arabica*. On the basis of GUS transient expression, survival and regeneration of the tissues, the authors determined that torpedo embryos were the best material for biolistic gene delivery. The same authors applied the improved conditions to transform *C. arabica* also with the complete pUBC plasmid (Sardana *et al.*, 1996; Cheng *et al.*, 1998) and the genetic cassette Ubi-*cry*-Nos (promoter-coding sequence-terminator). Such modification of the transformation procedure avoids or eliminates the negative effects attributed to the backbone of the vector of transformation that could be responsible for transgenic silencing, besides the number of foreign sequences introduced in the plant genome, including genes of resistance to antibiotics, which is controversial from the point of view of biosafety.

2.2.2 Indirect gene transfer

Hatanaka *et al.* (1999) achieved the first successful *A. tumefaciens*-mediated transformation of *C. canephora* plants exhibiting strong GUS stable expression. Leroy *et al.* (2000) also reported transformation and efficient regeneration of coffee plants of both *Coffea* sp. containing *uidA* and *cryIac* genes. Ribas *et al.* (2006a) also transformed *C. canephora* explants submitted to sonification during immersion in a suspension of an *A. tumefaciens* strain encoding *uidA* and *bar* genes and regenerated transformed plants. Moreover, Canche-Moo *et al.* (2004) transformed leaf explants through *A. tumefaciens*-mediated transformation involving a vacuum infiltration protocol in a bacterial suspension, followed by a step of somatic embryogenesis induction.

A. tumefaciens-mediated transformation has also served to induce stable gene silencing through RNAi technology of genes encoding theobromine synthase (Ogita *et al.*, 2004) and *NMT* (Kumar *et al.*, 2004) respectively, both genes involved in caffeine biosynthesis, in both *C. arabica* and *C. canephora* species. Ribas *et al.* (2005b) achieved inhibition of ethylene burst in *C. arabica* by means of introducing the transgene in antisense orientation.

Agrobacterium rhizogenes-mediated transformation in both *C. canephora* and *C. arabica* species was first reported by Spiral *et al.* (1993) and Sugiyama *et al.* (1995), respectively. Leroy *et al.* (1997) also achieved stable transformation of somatic embryos of both *Coffea* sp. following the protocol developed by Spiral *et al.* (1993). Kumar *et al.* (2006) described an adapted method for *A. rhizogenes* sonication-assisted embryo transformation. Their technique allowed the transformation and direct regeneration of transformants through secondary embryos by-passing an intervening hairy root stage. Alpizar *et al.* (2006a) developed an *A. rhizogenes*-mediated transformation protocol that enables efficient and rapid regeneration of transformed roots from hypocotyls of zygotic embryos and subsequent production of composite plants (transformed roots induced on nontransformed shoots) (Figures 3a, b, and c). This methodology was specifically developed for functional analysis of genes involved in resistance to root-specific pathogens like nematodes and/or in plant morphology and development. The authors demonstrated that the *M. exigua* root-knot nematode could normally proliferate in transgenic roots (Figures 3d, e, and f) and that consequently this transformation methodology could efficiently be applied for the functional analysis of the *Mex-1* resistance gene.

2.3 Selection of Transformed Tissue

Although in most coffee transformation reports, T-DNA transfer has been done through the use of binary vectors containing both the genes of interest and one or various selection marker(s) genes, few works have compared different concentrations and timings of antibiotic selective markers (*hpt* hygromycin-R, *nptII* kanamycin-R) or herbicide (*csr1-1* chlorsulfuron-R, *bar* ammonium glufosinate-R, *ppt* phosphinothricine-R) in order to find that allow best rates of transformed plant regeneration.

The first works in coffee transformation were done using kanamycin. However, this antibiotic has exhibited contradictory results as potential selection agent for transformed coffee embryos. Barton *et al.* (1991) and Spiral *et al.* (1993) concluded that kanamycin possesses poor selective capacity since nontransformed somatic embryos

Figure 3 *A. rhizogenes*-mediated transformation of coffee roots. (a) Aspect of branched transgenic roots on nontransgenic stems (composite plants) 12 weeks after *A. rhizogenes* infection on hypocotyl. (b) Histochemical localization of β -glucuronidase (GUS) gene expression in transgenic roots of *C. arabica* transformed with the p35S-gusA-int gene construct. The different tissues actively expressing the GUS gene are stained in blue. (c) Selection of transformed roots using GFP epifluorescence; the green fluorescence is observed specifically on transformed roots. (d) *C. arabica* composite plants in soil substrate ready for nematode inoculation in resistance tests. (e and f) Proliferation of the *M. exigua* root-knot nematode on *C. arabica* composite plants obtained after transformation with *A. rhizogenes*. (e) Gall symptoms caused by *M. exigua* on transformed roots of susceptible *C. arabica* var. Caturra 4 months after nematode inoculation. (f) GUS expression in feeding sites induced by *M. exigua* in transformed roots (var. Caturra)

could regenerate even at high concentration doses (400 mg l^{-1}), whereas Giménez *et al.* (1996) found that secondary somatic embryogenesis was inhibited at 50 mg l^{-1} of kanamycin. Giménez *et al.* (1996) and van Boxtel *et al.* (1997) agreed that embryogenic suspension cultures showed tolerance to 400 mg l^{-1} of kanamycin. Despite the previous warnings, kanamycin was recently used at 400 mg l^{-1} by Cunha *et al.* (2004) and at 100 mg l^{-1} by Canche-Moo *et al.* (2006), both achieving acceptable regeneration of transformed embryos. Hatanaka *et al.* (1999), Naveen *et al.* (2002), Mishra and Sreenath (2004) and Ogita *et al.* (2004) observed that hygromycin at $50\text{--}100 \text{ mg l}^{-1}$ allowed an acceptable regeneration frequency of *A. tumefaciens*-mediated transformed somatic embryos (Figures 2a, b, c, and d). Kumar *et al.* (2006) using *A. rhizogenes*-mediated transformation reported that 20 mg l^{-1} hygromycin interfered with secondary embryos growth and therefore suboptimal levels of selection pressure (5 mg l^{-1}) were employed during early embryogenesis development in order to retain nature of the transformed cell. Because of the low selection efficiency of antibiotics in coffee along with biosafety concerns about transferring of bacterial antibiotic resistance markers to plants and from these to animals or humans, coffee transformation strategy turned into the utilization of other types of selection markers as herbicide selection or positive selection in order to avoid this potential biohazard.

van Boxtel *et al.* (1997) proposed a “hybrid” protocol for selection of coffee transformed tissues, where kanamycin should be used only during early phase of callus development (100 to 200 mg l^{-1}) with subsequent use of the nonselective pre-emergence herbicide glufosinate ammonium (3 mg l^{-1}) on later developmental stages of somatic embryogenesis. van Boxtel *et al.* (1997) and Fernandez-Da Silva and Menéndez-Yuffá (2004) showed that low concentration of glufosinate (6 mg l^{-1}) were enough to inhibit nontransformed callus growth. Subsequent works carried by Ribas *et al.* (2005a, 2006a) confirmed the reliability of *bar* gene (which inactivates the herbicide ammonium glufosinate) as a selection marker to regenerate only transformed somatic embryos in both *C. canephora* and *C. arabica*. Leroy *et al.* (2000) have used the herbicide chlorsulfuron as selectable marker with gene *csr1-1* from

A. thaliana, which was effective in the same cultivated species at a concentration of $80 \mu\text{g l}^{-1}$. Later works also succeeded in regenerating transformed plantlets containing *ppt* gene, which confers resistance to phosphinothricin on selective medium containing $10 \mu\text{M}$ of the herbicide (Cruz *et al.*, 2004).

Other marker genes like phosphomannose isomerase (*pmi*) (Joersbo *et al.*, 1998) and xylose isomerase (*xylA*) (Haldrup *et al.*, 1998) have started to gain attention for their use in coffee genetic transformation. They differ from conventional (antibiotic or herbicides) selection markers as they are based on supplementing the transgenic cells with a recovery metabolic advantage rather than killing transgenic shoots after transformation (Joersbo, 2001). In coffee, Samson *et al.* (2004) tested the regeneration of somatic embryos in presence of mannose or xylose in media devoid of glucose and sucrose, and demonstrated that they were able to regenerate on explants cultured in the presence of mannose as sole carbohydrate source, but not in different concentrations of xylose, indicating thus the potential use of *XylA* gene as a positive selection marker in coffee transformation.

Recently, following environmental concerns about transferring herbicide resistance through natural pollination to nontransformed related plant species growing near the transgenic crop fields, along with the aim of simplifying transformation procedures, visual markers started to replace those based on herbicide selection. In that direction, Ogita *et al.* (2004) and Canche-Moo *et al.* (2006) used *gfp* and *DsRFP* reporter genes respectively for visual selection of somatic embryos of *C. canephora* following *A. tumefaciens*-mediated transformation. First report of complete selection of coffee transformed tissues without using any marker gene was achieved by Alpizar *et al.* (2006a), after selection of putative *A. rhizogenes* transformed roots through histochemical GUS assay (Figure 3b). The selection protocol was recently optimized using GFP epifluorescence and transformed roots were easily selected observing the green fluorescence on living roots (Alpizar *et al.*, 2006b) (Figure 3c). Transformed plants bombarded with the plasmid pUBC or the genetic cassette (Ubi-cry-Nos) were detected by PCR for the gene *cryIac* applied to all the regenerated plants, avoiding completely the use of reporter

or marker genes (De Guglielmo and Menéndez-Yuffá, unpublished results).

2.4 Regeneration of Transformed Whole Plants

The long life cycle of coffee tree calls for stability of the transgenes over several years and, until now, regeneration of stable transgenic coffee has scarcely been studied and seems still far from suitable to be used in routine for the different *Coffea* species. First regeneration of transformed *C. canephora* was achieved by Spiral *et al.* (1993) and for *C. arabica* by Sugiyama *et al.* (1995). In both these studies, transformed plantlets were regenerated from *A. rhizogenes*-mediated transformed somatic embryos and roots respectively; however, in these studies the regeneration protocol was laborious and plants showed a “hairy” phenotype with short internodes and stunted growth. Since the works of Yasuda *et al.* (1985) van Bostel and Berthouly (1996) who developed optimized protocols for direct and indirect somatic embryogenesis from coffee leaves, efficient regeneration of somatic embryos and plantlets was available for genetic transformation. The direct somatic embryogenesis is preferably used for *C. canephora* and the indirect one for *C. arabica*. The use of embryogenic tissues is often preferred to somatic embryos and become the most common way for coffee transformation (see Table 1). Such technique was later used by Leroy *et al.* (2000); however, embryogenic callus was induced only in 1.0% and 0.1% from total *A. tumefaciens*-mediated transformation events for *C. canephora* and *C. arabica*, respectively. From this callus, only 30% (*C. canephora*) and 10% (*C. arabica*) developed into secondary embryos, and from these, only 50% regenerated into plantlets. The previous results clearly demonstrated the genotype effect on coffee transformation, which is more efficient with *C. canephora*.

Ogita *et al.* (2004) developed an advantageous method that consisted in the production of direct somatic embryos directly from the epidermal tissues of the initial embryos (without callus formation and where somatic seedlings stage is reached within 3–6 months). Kumar *et al.* (2006) reported that regeneration of coffee plantlets following *A. rhizogenes*-mediated transformation

of somatic embryos was barely efficient (only 3% of total transformation events). They also described some plantlets exhibiting a “hairy root” phenotype with abnormal elongation and brittle and wrinkled leaves phenotype. However, the percentage of plantlets in the previous study with aberrant phenotype was significantly low compared with the results previously described by Sugiyama *et al.* (1995), who reported that all regenerated coffee plantlets showed a “hairy” phenotype. Such abnormal phenotype is stable as demonstrated by Perthuis *et al.* (2005) who showed that four out of the nine independently transformed *C. canephora* clones obtained with *A. rhizogenes* were still displaying this phenotype in field conditions, however, all these plants died rapidly after planting.

Although a considerable number of publications have reported the regeneration of transformed coffee plants, all plants from such experiments were maintained in transgenic greenhouses. Perthuis *et al.* (2005) reported the sole work of successful establishment of a batch of transformed coffee plants in field condition. Alpizar *et al.* (2006a, b) developed an efficient protocol for rapid regeneration of transformed roots from hypocotyls of zygotic embryos, and subsequent production of composite plants (transformed roots induced on nontransformed shoots) (Figures 3c and d). Nematode infection of such roots done in nursery conditions revealed no difference in the number of extracted nematodes between the transformed and nontransformed roots within two *C. arabica* varieties, resistant or susceptible to root-knot nematode, *M. exigua* (Figures 3e and f). The authors also demonstrated that transformed roots did not exhibit “hairy” disturbed phenotype and retained the resistance/sensibility phenotype of varieties from which they are derived.

2.5 Testing the Expression of Transgenes

2.5.1 Herbicide resistance

Leroy *et al.* (2000) regenerated transformed explants expressing resistance to chlorsulfuron. However, not all exhibited amplification of *csr1-1* gene, demonstrating the important occurrence of escapes during herbicide selection. Apart from chlorsulfuron, selection of transgenic

coffee plant has also been conducted by means of regenerating somatic embryos encoding *bar* gene on selective medium containing ammonium glufosinate (Ribas *et al.*, 2006a). Regenerated plants supported up to eight times the herbicide doses recommended for field applications. Transgenic plants were sprayed with the herbicide ammonium glufonate under greenhouse conditions and showed no phytotoxicity symptoms.

2.5.2 Pathogen resistance

Reports about coffee genetic engineering approach to insect resistance had increased considerably during the last few years, but till date no resistance to coffee berry borer (CBB) or CLM has been reported in *Coffea* sp. In the case of CLM, research has focused primarily on the use of *cry1Ac* gene from *Bt*, which possesses the most efficient δ -endotoxin against leaf miner (*Perileucoptera coffeella*) (Guerreiro *et al.*, 1998). Leroy *et al.* (2000) described achieving transformed plants in *C. canephora* with the synthetic version of this gene and expressing resistance to the insect in greenhouse conditions. Perthuis *et al.* (2005) reported that such resistance was stable and operationally effective after six releases of a natural population of *P. coffeella* during 4 years of field assessments. On other hand, production of transformed coffee plants with resistance to CBB was actually conducted by Cruz *et al.* (2004) with the α -*All* gene from common bean. The authors achieved transformation of *C. canephora* plants with this gene and bioassays with the insect are underway to confirm functional validation of its proteins in coffee (Cruz *et al.*, 2004). Following recent achievements in other crops, gene pyramiding could be envisaged in coffee in order to introduce a large number of resistance genes to diverse races of one pathogen or combined different pathogens.

2.5.3 Physiological traits

Ribas *et al.* (2005b) achieved inhibition of the ethylene burst by introducing the 1-aminocyclopropane-1-carboxylic acid (*ACC*) oxidase gene in antisense orientation; this technique would permit the understanding of

genes involved in fruit maturation and ethylene production. Satyanarayana *et al.* (2005) reported the cloning of the promoter of *NMT* gene involved in caffeine biosynthesis pathway. The authors mentioned that current efforts are focused on the use of this promoter sequence for down-regulation of *NMT* gene through transcriptional gene silencing. The recent cloning of the first promoter for the gene involved in caffeine biosynthesis (Satyanarayana *et al.*, 2005) together with the near identification of genes involved in sucrose and drought tolerance metabolism (Pot *et al.*, 2006) opens up the possibility for coffee plant transformation to validate and study the molecular mechanisms that regulate the production of these important targets for *Coffea* sp. cultivation.

2.6 Regulatory Measures

International agreements concerning genetically modified (GM) coffee do not exist in the coffee industry. However, there is a large consensus (ICGN for instance) within the coffee industry to avoid the commercialization of GM coffee and encourage to some extent the research and the knowledge in relation with coffee genomics and genetics including genome functional analysis using transgenics approach.

3. FUTURE ROAD MAP

3.1 Expected Products

Biotechnology offers new opportunities and technologies applicable to coffee agriculture and provides the means for addressing many constraints placed upon crop productivity by biotic and abiotic stresses. Possible applications include, engineering insect-pest resistance, developing male sterility for production of F₁ hybrids, incorporating pathogen resistance, drought and frost resistance, and gene manipulation for producing varieties with caffeine-free beans, uniform ripening, and improved cup quality characteristics. Several new applications have been suggested for the transgenic coffee and in some cases preliminary investigations have been initiated.

Availability of characterized genes is the driving force for developing biotech crops. Till recently, the complete sequences of only a few coffee genes were reported and even fewer genes were characterized (Stiles, 2001). Research programs are currently being implemented in coffee to identify and isolate genes of interest for agronomic, as well as, cup quality characteristics and the situation is changing rapidly. International Network on Coffee Genomics (ICGN) was launched in 2005 to facilitate exchange of genomic resources. The recent incorporation of coffee in the SOL (Solanaceae) genomics network project (Mueller *et al.*, 2005; Tanksley, 2006) is also likely to accelerate the identification of agronomically interesting genes. Coffee, as a member of the family Rubiaceae is distantly related to the model species *Arabidopsis*. A computational comparison of the coffee EST-derived unigene set with the sequence databases for *Arabidopsis* and Solanaceous species (e.g., tomato, pepper), indicate that Solanaceae crops are much better genomic models for coffee than *Arabidopsis* (Lin *et al.*, 2005). These results are consistent with the fact that coffee and Solanaceous species share very similar chromosome architecture and are closely related, both belonging to the Asterid I clade of dicot plant family. Moreover, the ability to identify orthologous genes between coffee and tomato opens up the door to eventually developing detailed comparative maps and to sharing of genomic and biological tools/discoveries (Lin *et al.*, 2005). Comparative genomics is forging a new identity for coffee breeding/improvement and opening the door to an unparalleled rate of gene discovery (Tanksley, 2006). Progress made in coffee in several research labs are likely to yield gene sequences of interest from *C. arabica* and *C. canephora* for resistance to leaf rust, nematodes, beverage quality, etc. By screening for homology, it is hoped to access genes coding for beneficial traits from wild relatives of coffee.

3.1.1 Resistance to insect pests and nematodes

The major pests attacking coffee include CBB (*Hypothenemus hampei*) (Coleoptera, Scolytidae), leaf miner (*Leucoptera* spp.), white stem borer (*Xylotrechus quadripes*), root nematodes (*Meloidogyne* spp. and *Pratylenchus* spp.) (Crowe, 2004; Castillo

and Wintgens, 2004; Lan and Wintgens, 2004). The CBB is present worldwide and considered to be the most devastating and economically important insect pest of coffee. If uncontrolled, the pest can reach at very high infestation levels. Leaf miner is an economically important pest in East Africa and Brazil and is responsible for leaf degradation and subsequent yield decrease. White stem borer (WSB) is a serious pest of arabica coffee in India, China, and other East Asian countries. Developing arabica selections with resistance to WSB is the top most research priority for India.

Both CBB and WSB belong to the order Coleoptera (beetles). There appears to be no naturally occurring resistance gene in coffee gene pool for CBB. The robusta is generally resistant to WSB but the pure arabica as well as robusta-introgressed arabica selections are susceptible to WSB. Although chemical and biological control mechanisms are adapted to combat these insect pests, the fight against insects represents the priority for numerous producing countries and the introduction of effective resistance through biotechnology is envisaged as a serious solution to improve the lives of coffee farmers. While pesticides are very effective in combating the immediate problem of pest attack on crops and have been responsible for dramatic yield increases in crops subject to serious problems, nonspecific pesticides are harmful to beneficial organisms, including predators and parasitoids of the target pest species. The drawbacks of unconstrained and indiscriminate insecticides usage have become apparent, not only in respect to the development of pest resistance, but also in terms of ecological impact. Some of the pesticides used to control coffee pests have entered the banned list.

For insect resistance, several different classes of bacterial plant and animal-derived proteins have been shown to be insecticidal toward a range of economically important pests from different orders (Ferry *et al.*, 2004). Of these, *Bt* toxins are the most commercially relevant, since *Bt*-expressing crops are the only insect-resistant transgenic crops to have been commercialized to date. *Bt*, a soil dwelling bacterium, colonizes and kills a large variety of host insects, but each strain has a high degree of specificity. *Bt* strains and their insecticidal crystal (*Cry*) proteins (ICPs) produced during sporulation have been used extensively as eco-friendly biopesticides in agriculture all over the

world for the past four decades. With the advent of molecular biology and genetic engineering it has become possible to introduce ICPs of *Bt* in crop plants to impart insect resistance. More than 40 different classes of *Bt* toxins have been identified on the basis of amino acid sequence homology (www.biols.susx.ac.uk/Home/Neil-Crickmore/Bt). This database could be a valuable resource for identifying candidate *Bt* genes against target pests of coffee.

Using *A. tumefaciens*-mediated transformation, Spiral *et al.* (1999) successfully transferred the *cry1Ac* gene into *C. canephora* and *C. arabica* genotypes for imparting resistance to leaf miner. Molecular characterization of transformed plants showed that 69% of them carried a unique copy of T-DNA and Cry1Ac protein expression in leaves was obtained in 18 of 23 plantlets tested (Leroy *et al.*, 2000). Three different levels of resistance could be measured with some highly resistant plants, some highly susceptible and fully susceptible plants. Transformed plants highly resistant to leaf miner under greenhouse conditions were tested under field conditions in French Guyana for 4 years for field resistance (Perthuis *et al.*, 2005, 2006) in an experiment with 54 transformation events. Approximately 70% of the events tested were resistant to leaf miner. They also observed that the transformed plants presented similar growth and development compared to control plants. It was the first time that an important agronomic trait was introduced into a coffee plant and also field tested. Unfortunately, the field trial was vandalized and the experiment had to be suspended (Montagnon, 2005).

Mendez-Lopez *et al.* (2003) demonstrated that the *Bt* serovar *israelensis* was highly toxic to CBB during the first instar of the larvae. Protection against coleopteran pests has been achieved in corn and potato using *Bt* genes. This is an important example of the potential utilization of the genetic transformation technology, since to date, there is no reported source of resistance to CBB in *Coffea* species and the chemical control of the insect is difficult due to its life cycle, spent most of the time inside the berry. In another approach to control CBB, an α -amylase inhibitor from *Phaseolus vulgaris* has been considered as a target gene for introduction in coffee plants. *In vitro* assays demonstrated that this protein can inhibit CBB growth and development (Grossi de

Sa *et al.*, 2004). An international collaborative project implemented by Central Coffee Research Institute (CCRI) from India and CIRAD from France identified two new *Bt* Cry36-like toxins to be active against CBB and WSB larvae.

Control of CBB using transformed plants could represent an additional health benefit. In *Bt* corn, a decrease in both *Fusarium* and the mycotoxin fumosin has been reported (Munkvold *et al.*, 1999). Since CBB infestation could facilitate fungi penetration in coffee, lesser CBB infestation could reduce amount of *Aspergillus flavus* and *Aspergillus ochraceus* and consequently the amount of ochratoxin produced in the coffee, which is of major concern in the most important coffee markets in Europe and the United States (Ribas *et al.*, 2006b).

Cultivation of coffee with insect resistant transgenes has to be accompanied by intense insect management studies. The constant selection pressure of the plants on the insect population will probably favor the emergence of insect resistant populations. Since coffee plantations can remain productive for as long as 30 years without replantation of the trees, strategies for pest management must be implemented together with the introduction of insect-resistant transgenic coffee plants, such as the use of cultivated lines of nontransgenic coffee, biological control with natural predators and other agronomic practices to keep resistant insect populations under control (Leroy *et al.*, 2000; Ribas *et al.*, 2006b).

The main *C. arabica* cultivated varieties were shown to be susceptible to the sedentary endoparasitic root-knot nematodes (*Meloidogyne* spp.) (Campos *et al.*, 1990). In many production regions, *Meloidogyne* is a major agricultural constraint and can result in significant drops of production. So far, more than 15 species have been reported as parasites of coffee. Sources of resistance specific to root-knot nematodes have been identified in coffee trees (Bertrand *et al.*, 2001) and the *Mex-1* gene conferring resistance to *M. exigua* in *C. arabica* is in the process of being isolated (Noir *et al.*, 2003).

Genetically improving plants for resistance to nematodes requires increase in knowledge regarding resistance genes and associated mechanisms. Molecular dissection of resistance genes and better understanding of basis and evolution of resistance specificity would contribute to an enhanced

durability and utility of the identified resistance genes. For this purpose, the development of a genetic transformation procedure and additional tools for functional analysis that enable rapid validation and study of resistance genes to nematodes would be extremely useful.

Hairy roots were proposed as an easy system for testing nematode resistance in crop plants and were successfully used to study function of *Mi* and *Hs1pro-1* gene in tomato and sugar beet, respectively (Cai *et al.*, 1997; Remeus *et al.*, 1998; Kifle *et al.*, 1999; Hwang *et al.*, 2000). Nevertheless, difficulty in maintaining axenic culture conditions in a system with three organisms, i.e., plant/nematode/*A. rhizogenes* (Narayanan *et al.*, 1999) and the problematic difference between natural root environment and the use of sterilized nematodes and plant material devoid of aerial system when studying plant–nematodes interactions have been reported. An alternative strategy was developed in coffee for studying the function of genes in roots. It consists of using “composite” plants that can be efficiently and rapidly generated by inducing transformed roots on nontransformed shoots after inoculation with *A. rhizogenes* (Alpizar *et al.*, 2006a, b). These authors described (i) the development of a convenient *A. rhizogenes*-mediated transformation protocol for *C. arabica* enabling efficient and rapid regeneration of transformed roots from the hypocotyls of germinated zygotic embryos, and the subsequent production of composite plants without selection with antibiotics or herbicides (Figures 3a, b, and c); and (ii) the successful infection of transformed roots belonging to composite plant expressing the *gus* and *gfp* genes with the root-knot nematode, *M. exigua* (Figures 3d, e, and f). Composite plants offer the major advantage over axenic hairy root cultures of generating information at the whole plant level and give the possibility to realize functional analysis studies in nonaxenic conditions. To our knowledge, composite plants have never been used to study plant–nematode interaction.

A localized genetic map of the chromosome carrying the major dominant *Mex-1* gene conferring resistance to *M. exigua* in *C. arabica* was constructed (Noir *et al.*, 2003) and the physical mapping of the *Mex-1* region is currently pursued. We will soon apply this plant composite technique to validate *in vivo* the *Mex-1* gene

by functional complementation. This technique could also be applicable to functional analysis studies of coffee genes involved in the resistance to other agronomically important nematode species (*M. paranaensis*, *M. arabicida*, *M. incognita*), in root development or in mycorrhizal symbiotic associations.

3.1.2 Decaffeinated coffee

Caffeine is considered as the most widely used psychoactive substance in the world. It is present in leaves, seeds, and fruits of more than 60 plant species, of which coffee, tea, kolanuts, guarana seeds, cocoa are the most popular ones. Most of the caffeine consumed comes from dietary sources such as coffee, tea, cola drinks, and chocolate. In humans, sleep seems to be the physiological function most sensitive to caffeine. Caffeine prolongs sleep latency, shortens total sleep duration, but preserves the dream phases of sleep. An average concentration of 60–85 mg of caffeine per cup has been assumed for instant, roasted, and ground coffees, respectively (Schilter *et al.*, 2001). The most notable behavioral effects of caffeine occur after low to moderate doses (50–300 mg); these are increased alertness, energy, and ability to concentrate. Higher doses of caffeine rather induce negative effects.

An area of considerable interest for coffee biotechnology is caffeine biosynthesis. Caffeine (1,3,7-trimethylxanthine) belongs to the category of plant alkaloids called methylxanthines. The first step, unique to caffeine biosynthesis pathway, is the methylation of xanthosine at N⁷ position by xanthosine N⁷ methyl transferase. Sequence of gene coding this enzyme is reported (Moisyadi *et al.*, 1999). Molecular cloning and functional characterization of three distinct N-methyltransferases involved in the caffeine biosynthetic pathway in coffee plants are also reported (Ogawa *et al.*, 2001; Uefuji *et al.*, 2003).

The average content of caffeine is 1.2% in arabica and 2.2% in robusta showing a marked interspecific difference as well as high intraspecific variability. Naturally decaffeinated arabica coffee plant was discovered recently (Silvarolla *et al.*, 2004). Coffee is primarily used as a stimulating beverage with characteristic organoleptic properties. There is a sizeable demand for decaffeinated

coffee because caffeine can adversely affect sensitive individuals by triggering palpitations, increased blood pressure, and insomnia. Market for decaffeinated coffee has increased to about 10% of coffee consumption worldwide. The chemical and physical methods used by the industry to produce decaffeinated coffee are expensive and affect the cup quality due to loss of key flavor compounds. Consequently, research in the biological realm for identifying a suitable decaffeinating agent has gained momentum.

The transgenic technology can be used to down-regulate the genes encoding enzymes responsible for caffeine biosynthesis. Recently, transgenic coffee plants were regenerated in which the gene encoding theobromine synthase was repressed by RNAi. Ogita *et al.* (2002, 2003, 2004) reported construction of transgenic coffee plants (*C. canephora*) in which expression of the gene encoding theobromine synthase (*CaMXMT1*) was repressed by RNAi. The caffeine content (measured in the leaves) of these plants was reduced by up to 70% indicating that it should be feasible to produce coffee beans that are genetically deficient in caffeine. Current evaluation in field trials should soon confirm the reduced caffeine content of the seeds. The main psychoactive component in coffee is caffeine. Caffeine content does not seem to have any direct effect on sensory quality (Illy and Viani, 1995). Hence, flavor of the genetically decaffeinated coffee is likely to be the same as regular coffee. However, doubts persist on the quality of this coffee because the accumulation of theobromine in the seeds could lead to adverse effects on coffee quality. Caffeine is also known to give resistance against insect pests. In view of this, it would be necessary to evaluate the reaction of decaffeinated coffee plants to insect pests. Instead of turning off the caffeine biosynthesis in the entire plant, the research can be focused to produce only caffeine-free beans for retaining the beneficial effects of coffee for plant protection.

3.1.3 Resistance to abiotic stresses

Abiotic stresses, such as freezing and drought, are the major climatic limitations for coffee production. As explained recently in a review by DaMatta and Ramalho (2006), these limitations are expected to become increasingly important

in several coffee growing regions due to the recognized changes in global climate, and also because coffee cultivation has spread toward marginal lands, where water shortage and unfavorable temperatures constitute major constraints to coffee yield. For example, periodic freezes, experienced in certain production areas of Brazil disrupt commodity markets. The introduction of frost tolerance in coffee through genetic transformation would be of great importance in alleviating the disruption that a frost can cause to coffee industry. Identification of drought tolerance genes by genetic engineering may be a way forward for marginal environments, complementing the breeding work and marker-assisted selection for tolerance that explores the natural allelic variation at genetically identifiable loci.

In most arabica coffee growing areas, the annual rainfall is in the range of 1500 to 2500 mm. Ideally, rainfall should be well distributed over a period of about 9 months with a single dry season of about 3 months coinciding with the harvest season. *C. canephora* (robusta coffee) is indigenous to West and Central African regions characterized by abundantly distributed rainfall and atmospheric humidity frequently approaching saturation (Charrier and Eskes, 2004). Arabica is generally more tolerant to water stress than robusta, at least partly as a result of a more extensive and deeper root system. *C. racemosa* is mentioned as a good source for drought tolerance.

Drought is an environmental factor that produces water deficit or water stress in plants. Inadequate and uneven distribution of rainfall causes drought condition in coffee, which affects the vegetative growth, induces floral abnormalities, and results in poor fruit-set and less crop. In Brazil, with a major area of production, robusta coffee has been largely cultivated in regions where water availability constitutes the major environmental constraint affecting crop production. Even short periods of drought can substantially decrease coffee yields and consequently irrigation is indispensable for production (Pinheiro *et al.*, 2005). A similar situation exists in India where robusta contributes around 60% of its production (Sreenath and Prakash, 2006). There is a prolonged drought of around 4 months in coffee production areas in India.

The causes of the differences in clonal tolerance to drought in robusta coffee still remain largely

unknown. Pinheiro *et al.* (2005) conducted studies to better understanding of the physiological and morphological basis of drought tolerance in robusta coffee and found that drought tolerance is associated with rooting depth and stomatal control of water use in clones of *C. canephora*. Some naturally occurring drought-tolerant plant species seem to employ deep and dense root systems to maximize water uptake. In the Brazilian Coffee Functional Genomics Program, research is being carried out by several groups aiming at identifying genes involved in biotic, as well as, abiotic (drought, salinity, and cold) stresses, apart from genes involved in flowering, fruit development and quality (Andrade *et al.*, 2006). Increasing knowledge of drought stress adaptation processes has been key to develop genotypes with improved tolerance to dehydration. The most successful or promising cases of genetic engineering for drought tolerance include the use of functional or regulatory genes, as well as, promising technologies such as transfer of transcription factors. In recent years, physiological and molecular bases for plant responses to drought and concurrent stresses such as high temperature and irradiance have been the subject of intense research (Chaves *et al.*, 2003; Chaves and Oliveira, 2004; Coraggio and Tuberosa, 2004). However, such studies are still very limited in coffee. Some studies are done in Brazil and India to understand the molecular basis of drought tolerance in coffee.

The recent progress in gene discovery and knowledge of signal transduction pathways is raising the hope of engineering important traits by manipulation of one single gene, downstream of signaling cascades with putative impact on more than one stress type (Chaves and Oliveira, 2004). Moreover, in genetic engineering, it is important to mimic nature and activate, at the correct time, only the genes that are necessary to protect the plants against stress effects. This may be achieved by using appropriate stress-inducible promoters and will minimize effects on growth under nonstress conditions, which is essential for agricultural crops.

Among the genes that are known to respond to drought stress and which are being manipulated by genetic engineering, some encode enzymes involved in metabolism (for example, linked to detoxification or osmotic response), others are active in signaling, in transport of metabolites

(for example, the proline transporter), or in regulating plant energy status (Chaves and Oliveira, 2004; Coraggio and Tuberosa, 2004). The molecular understanding of stress perception, signal transduction, and transcriptional regulation of these genes, may help to engineer tolerance to multiple stresses. Advances in the molecular biology of stress response in tolerant organisms are leading to a number of possibilities concerning regulatory genes that may be used in agricultural programs, not only to ensure survival under water deficit, but also to guarantee a reasonable productivity under reduced water availability.

3.1.4 Pathogen resistance

Coffee diseases are often classified as root diseases, diseases of stems and branches, foliage diseases, and diseases of berries and beans. Coffee diseases are mostly caused by fungi. The best-known disease of coffee is leaf rust (caused by the fungus *H. vastatrix*) which was first recorded in Sri Lanka in the 1860s and has since spread around the world (Muller *et al.*, 2004). The only satisfactory long-term solution to leaf rust is to plant resistant cultivars. The relevance of durable host resistance to coffee leaf rust (CLR) can be deduced from its economic damage to world arabica coffee production, which has been estimated at US\$ 1–2 billion per year due to crop losses (20–25%) and the need to apply cultural and chemical control measures (10% of production costs) (Van der Vossen, 2001). Resistance to CLR is conditioned primarily by a number of major (S_H) genes and coffee genotypes are classified in resistance groups according to their interaction with physiological races of the rust pathogen (Van der Vossen, 2001). India has a long history of arabica coffee breeding dominated by repeated occurrence of new physiological races of CLR, probably due to the warmer and wetter climatic conditions in major coffee growing areas. Resistance to CLR in robusta coffee is usually a secondary character of selection and based on individual plant, clone, or family scores for field infection (Van der Vossen, 2001).

The CBD caused by the fungus *C. kahawae* can be a devastating anthracnose of developing berries in arabica coffee in Africa. The impact of the disease on productivity is stronger in high altitude plantations over 1500 m in the tropics,

but occasionally it takes hold in plantations at lower altitudes, which have specifically cold and damp microclimate (Muller *et al.*, 2004). CBD may cause crop losses of 50–80% in years favorable to a severe disease epidemic (prolonged wet and cool weather). Economic damage to arabica coffee production in Africa due to CBD alone (crop losses plus costs of control) is estimated at about US\$ 300 to 500 million per year (Van der Vossen, 2001). Breeding programs initiated about 30 years ago in Kenya and Ethiopia have been successful in developing new cultivars with high and apparently durable resistance to CBD (Van der Vossen, 2001).

Several other fungal and bacterial diseases may affect coffee (Muller *et al.*, 2004; Sreenath and Prakash, 2006), but only a very few of them have been targeted in breeding programs, notwithstanding considerable economic damage in certain coffee producing countries, because useful host resistance could not be detected in available coffee germplasm. A number of other fungal diseases attack the branches of arabica coffee causing dieback and sometimes death of the branch. These include *Koleroga*, thread blight or black rot (*Pellicularia koleroga* = *Koleroga noxia*) and pink disease (*Corticium salmonicolor*) (Muller *et al.*, 2004). The less virulent strains of *Colletotrichum coffeanum* occur in most coffee growing areas in the world and cause brown blight (anthracnose) on the ripening cherry and lesions on leaves and green wood. Other fungi that can attack the berries include *Cercospora coffeicola* causing warty disease and various species of *Fusarium*. Various microorganisms attack coffee beans and cause them to rot or develop off-flavors. This occurs either because of storage in damp conditions or as a result of damage by insects.

Arabica is far more susceptible to diseases than robusta coffee and in many countries diseases are the limiting factor to production. Most diseases can now be controlled by chemical means, but often with difficulty and considerable cost. The most satisfactory long-term solution is the selection and breeding of disease-resistant cultivars, which is a major aim of coffee breeding programs (Etienne *et al.*, 2002). Spontaneous accessions collected in the primary center of diversity appeared to constitute a valuable gene reservoir. To date, *C. canephora* provides the main source of disease and pest resistance traits not found in *C. arabica*, including CLR (*H. vastatrix*),

CBD (*C. kahawae*), and root-knot nematode (*Meloidogyne* spp.). Likewise, other diploid species present considerable interests in this respect. For instance, *C. liberica* has been used as source of resistance to leaf rust (Sreenivasan, 1989), while *C. racemosa* constitutes a promising source of resistance to the CLM (Guerreiro Filho *et al.*, 1999).

There are a number of distinct signaling pathways that induce a coordinated expression of sets of antifungal proteins and/or compounds (Thomma *et al.*, 2001). These pathways are commonly dominated by the small signal molecules that play a central role in the induction of the defense proteins: salicylic acid, jasmonic acid, ethylene, or certain reactive oxygen species (Feys and Parker, 2000; Grant *et al.*, 2000). Several other pathways inducing defense exist in addition. Induction of each of these signaling pathways leads to the induction of various defense compounds, including sets of antifungal proteins, phytoalexins, and enzymes involved in plant cell reinforcement (Stuiver, 2006). Understanding the specific induction of targeted pathways and which pathway is causing resistance to which fungus in coffee is important to exploit the strategy. The recent findings of early expressed genes in specific hypersensitive reaction (HR) in resistant coffee plants in response to a virulent races of leaf rust pathogen (Fernandez *et al.*, 2004) could give an insight into the defense pathways operating in coffee.

Resistance to leaf rust pathogen in coffee by S_H genes is reported to be due to hypersensitive reaction. Recognition of the fungal elicitor was determined genetically to occur through a resistance (R) gene product made by the plants. The recognition is highly specific and depends on the presence of the exact R gene and its cognate elicitor. In coffee at least nine S_H resistance genes are recognized that confer resistance to different physiological races of leaf rust pathogen. Stacking or pyramiding of “R” genes is considered as a strategy for providing durable resistance. In coffee, this strategy can be applied by molecular assisted selection.

Efforts have been concentrated on cloning coffee resistance genes toward achieving durable resistance. Using degenerate primers based on conserved motifs of nucleotide binding site (NBS) region of NBS-LRR resistance genes, coffee R-

genelike sequences (i.e., resistance gene analogs or RGAs) representing substantial diversity have been identified (Noir *et al.*, 2001; Sreenath *et al.*, 2002). Most coffee RGAs appear to be closely related by sequence to at least one known R-gene and may encode resistance gene products of as yet unknown specificity. Recently, the genetic and physical maps of two resistance genes have been established, i.e., *Mex-1* gene conferring resistance to the nematode *M. exigua* (Noir *et al.*, 2003) and the *S_H3* gene conferring resistance to rust (Prakash *et al.*, 2004). The genetic map of the *Ck1* gene conferring the resistance to the *C. kahawae* (CBD) has also been recently established (Gichuru *et al.*, 2006). After cloning and functional validation, all these resistance genes could represent good candidates for molecular marker-assisted selection.

3.1.5 Improvement in cup quality characteristics

The distinctive flavor of coffee is certainly the principal reason for the high acceptability of the beverage prepared from the roasted and ground beans. Cup quality has gained importance as a result of the growth of specialty coffee sector. Biotechnology will undoubtedly play a progressively more important role in increasing the knowledge on the chemical constituents and metabolic ways involved in the elaboration of quality.

Chemical constituents of coffee bean have been analyzed thoroughly in recent years (Flament, 2002). While 300 flavor compounds are detected in green coffee, 850 are detected in roasted coffee. New analytical techniques are giving better insight into the fundamental chemistry of specific precursors and pathways leading to key flavor compounds. The constituents of coffee beans include minerals, carbohydrates, proteins, caffeine, chlorogenic acids (CGA), glycosides, lipids, and those transformed or formed at roasting such as trigonelline and the volatile constituents that create the unique flavor. In recent years, large-scale genomic studies have been speeding up the process of gene identification. Screening of fruit specific EST libraries may lead to identification and characterization of key genes responsible for cup quality. Because of the complexity of the chemical composition of coffee beans there

could be several strategies for improving the cup quality characteristics. The role of three major constituents influencing the coffee flavor and taste, namely, trigonelline, CGA, and sucrose are considered in the following paragraphs.

While all coffee beans have a high trigonelline alkaloid content, *C. arabica* cultivars have a higher content (0.79–1.06% on dry matter basis, dmb) than *C. canephora* cultivars (0.66–0.68% dmb) (Stennert and Maier, 1994). At roasting temperature (240 °C) this alkaloid produces pyridines and pyrrole derivatives (De Maria *et al.*, 1994, 1996), which are important volatile coffee flavor components (Flament, 2002). Trigonelline is considered to be important for both taste and nutrition. Consequently, one objective of coffee breeding research programs is to increase trigonelline content in robusta green beans (Ky *et al.*, 2001a).

The CGA are ubiquitous in the plant kingdom. They are a family of esters of quinic acid with several hydroxycinnamic acids particularly caffeic, ferulic, coumaric acids. In green coffee beans, three classes represent about 98% of the CGA content (Morishita *et al.*, 1989): caffeoyl quinic acids (CQAs), dicaffeoyl quinic acids (di CQA), and feruloyl quinic acids (FQA). They are present in relatively large quantities in the coffee bean, as the CGA content varies from 6% to 7% in arabica beans and is about 10% in robusta beans. CGA in green beans are major precursors of phenolic compounds in roasted beans. They are mainly responsible for coffee bitterness (Leloup *et al.*, 1995). The difference in CQA content in *C. arabica* and *C. canephora* is a major element explaining different flavor characteristics between these coffees (Clifford, 1985a; Ky *et al.*, 2001b). CGA is a crucial parameter of breeding programs considering the high CGA content variations in the *Coffea* genus associated with their effects on organoleptic quality and disease resistance (Campa *et al.*, 2003). Contrary to the negative attributes imparting bitterness in the cup, recent research is revealing the beneficial effects of CGA due to their antioxidant properties. In view of this, there could be demand for both increased and reduced CGA in coffee depending on the consumer perception. Genetic manipulation of genes involved in CGA biosynthesis can serve either of the purposes by up- or down-regulating the pathway.

CGA are products of phenylpropanoid metabolism, one branch of the phenolic pathway. Phenylalanine ammonia-lyase (PAL) catalyzes the first step of the phenylpropanoid pathway leading to the synthesis of a wide range of chemical compounds including flavonoids, coumarins, hydroxycinnamoyl esters, and lignin (Hahlbrock and Scheel, 1989). Caffeoyl quinic acid (5-CQA) is the major soluble hydroxycinnamoyl ester accumulated in plants. Formed by esterification between a caffeic acid and a quinic acid, it is grouped with other hydroxycinnamoyl quinic acids (HQA), under the generic name “chlorogenic acids” (Clifford, 1999). The 5-CQA cell content was found to increase in transgenic tobacco leaves overexpressing the *P. vulgaris* PAL2 gene, indicating that PAL is a key enzyme for 5-CQA synthesis (Howles *et al.*, 1996). Recently, Mahesh *et al.* (2006) isolated and characterized a full-length *C. canephora* PAL cDNA and its corresponding genomic sequence. This achievement has opened up the possibility of manipulating the key control enzyme PAL in coffee, which in turn will be useful to regulate several traits like cup taste, antioxidant property, pathogen and pest resistance, etc.

The sucrose content of coffee beans is an important component of coffee flavor, the higher the sucrose content in green beans, the more intense will be the coffee cup flavor (Clifford, 1985b; De Maria *et al.*, 1996). Coffee flavor is developed during the roasting process from aroma precursors present in green beans. The aroma formation is very complex and includes Maillard and Stucker's reactions and flavor precursor degradation (De Maria *et al.*, 1994). Among them, sucrose, which is degraded to furans, is one of the most important (Clifford, 1985b; Dart and Nursten, 1985; De Maria *et al.*, 1996). In addition, the sucrose also reacts with amino acids producing pyrazines and carboxyl compounds also involved in flavor. The sucrose/amino acids ratio in green beans widely determines the profile of volatile compounds. In *C. arabica* green bean, sucrose content is higher than in *C. canephora*: 8.2–8.3% versus 3.3–4% on dmb. Recent success in cloning and sequencing of *C. canephora* sucrose synthase gene (*CcSUS2*) (Leroy *et al.*, 2005) has provided a tool for manipulating the sucrose content in coffee leading to improved cup quality characteristics.

3.1.6 Fruit ripening

Uniformity during fruit ripening is decisively related to cup quality in coffee, and consequently to the value of the product. Fruits at correct ripened stage produce the best organoleptic characteristics for coffee. The presence of green fruits and over-ripened fruits changes the acidity, the bitterness, and consequently the cup quality. There is a possibility to achieve uniformity in fruit ripening by controlling the action of genes involved in the last steps of the maturation process, which is triggered by ethylene. In coffee, as well as other climacteric fruits, a dramatic increase in ethylene biosynthesis promotes the subsequent steps of fruit ripening, with biochemical and physiological changes (Pereira *et al.*, 2005). To control coffee fruit maturation, two of the main genes involved in ethylene biosynthesis, namely, ACC synthase and ACC oxidase have been cloned (Neupane *et al.*, 1999; Pereira *et al.*, 2005). Introduction of the ACC oxidase gene in the antisense orientation is reported in *C. arabica* and *C. canephora* (Ribas *et al.*, 2003, 2005b). The effect of the transgene on fruit maturation and ethylene production are yet to be reported. The inhibition of genes downstream to the initial ethylene burst is also an option to control fruit maturation (Ribas *et al.*, 2006b).

3.2 Expected Technologies

3.2.1 Improved transformation systems

Development of efficient, genotype-independent transformation systems is the ultimate aim of all transgenic crop programs, but remains elusive due to variations in *in vitro* morphogenic response between even closely related cultivars. Despite significant advances over the last 15 years, coffee transformation is still very laborious, with bottlenecks in the methodology that makes it far from a routine laboratory technique. In order to achieve many of the transformation goals, genetic transformation technologies of coffee must continue to be improved. There are two possible applications for coffee genetic transformation: (1) as a tool for gene validation (functional genomics), (2) eventually on the long term, as a way to regenerate new improved transgenic varieties. For the two objectives, the current protocols have to be

improved, but depending on the type of utilization, the requirements can be different (for example, the absolute need of a cleaner process for transgenic varieties through elimination of marker genes).

3.2.2 Elimination of marker genes

Production of genetically transformed crop plants without marker genes is desirable, but remains technically demanding. At present, the regeneration system of coffee is tedious and not very efficient. As transgenic technologies are improved for the crop, progress will be made toward genetically transformed marker-free coffee plants. Recently, Alpizar *et al.* (2006a, b) with an *A. rhizogenes*-mediated transformation system, have reported the possibility to regenerate transgenic roots and composite plants without using marker genes. The visual identification of transgenic roots with *gus* and more efficiently with *gfp* reporter genes allowed an efficient selection. Such a system is currently investigated to regenerate whole transformed plants with an *A. tumefaciens*-mediated transformation protocol.

3.2.3 Control of transgene expression

Transgene products must be expressed in relevant tissues at levels that impart agronomically useful traits. This may be in the stem for *Bt* protection against stem borers, in the fruits against berry borer and CBD, in the leaves against leaf miner and leaf rust, in the roots against nematodes, and in the beans for modification of carbohydrate, protein, caffeine, or CGA for improved cup quality and postharvest characteristics. Levels of transgene expression must be maintained stably in the coffee plant over several years because of the perennial nature of the crop. Access to tissue-specific and inducible promoters is required for successful development of coffee functional analysis and transgenic coffee. Promoter for N-methyltransferase gene associated with caffeine biosynthesis was isolated from *C. canephora* (Satyanarayana *et al.*, 2005). GUS assays proved that the isolated promoter was able to direct the expression of the reporter gene in transgenic tobacco. Marraccini *et al.* (1999) cloned a complete 11S seed storage protein gene and carried out

promoter analysis in transgenic tobacco plants. They obtained about 1 kb of the promoter region and about 0.9 kb of the 3' region in addition to the coding region. Sequence analysis of the promoter region indicated several motifs that occur in other seed storage protein genes that are responsible for both temporal and spatial regulation. The seed specificity of the 11S storage protein promoter may make it a useful tool for coffee biotechnology. By varying the length of the promoter it should be possible to impart the desired level of expression in a tissue specific manner to coffee seeds. This technology might be used for expressing disease and pest resistance genes specifically in the seed at the desired amount. The promoter could also be used to express genes that affect quality factors involved in cup quality or soluble solids important to the soluble coffee market (Stiles, 2001).

Recently, ESTs for two major seed storage proteins of coffee (2S and 11S) have been identified and demonstrated that these proteins are expressed at different times during seed development (Lin *et al.*, 2005). A number of highly expressed genes that show high specificity for different stages of seed development as well as for the pericarp tissue that surrounds the seed have been identified (Lin *et al.*, 2005). These genes could lead to the promoters that can potentially be used to drive gene expression in specific stages/tissues of the coffee plant. Many of these genes are specific to defined periods of seed and/or pericarp development—both critically important for insect/pathogen resistance and determining the quality of the coffee bean with respect to commercial coffee products. Availability of these promoters and additional control elements developed through similar research programs are providing important new tools for improving transgene expression and producing coffee with beneficial traits. It is proposed to create a collection of promoters in the ICGN as a resource for functional analysis of coffee genes.

3.2.4 Transfer of multigene DNA fragments and modifying more complex traits

In many cases, the objective will be to transfer large segments of DNA such as BAC clones and cosmids or in the case of metabolic engineering to simultaneously integrate several genes into the

coffee genome and express them in a coordinated manner. Gene isolation by positional cloning frequently requires several rounds of transformation. Even in well-studied crops for which multiple DNA markers are available, it remains difficult to narrow down the chromosomal region of interest to a manageable size for gene identification (Tao *et al.*, 2002). To minimize the resources invested and to accelerate the process, recent research has shown that it is possible to use large DNA fragments in transformation experiments followed by analysis of transgenic plants to assess functional complementation. Vectors like BIBAC (binary bacterial artificial chromosome) (Hamilton *et al.*, 1996) and TAC (transformation-competent artificial chromosome) (Liu *et al.*, 1999), which are functionally analogous, were designed to have the characteristics of both BACs and binary vectors for *Agrobacterium*-mediated transformation. Another application can be the transfer of clusters of genes (naturally occurring or synthesized) into the plant nuclear genome. Consequently, several disease resistance coffee genes or different genes belonging to a same biochemical pathway can be inserted in one transformation step and subsequently inherited as a single locus. While such capacities are established for the other major crops, further research is required to develop transgenic systems in coffee to facilitate these aims.

1. INTRODUCTION

Cacao, *Theobroma cacao* L., is a small understory tree believed to have evolved in the lowland rainforests of the Amazon basin (Wood and Lass, 1985; Bartley, 2005). Today, cacao is grown throughout the humid tropics, often in agroforestry ecosystems with other fruits and commodity crops. The production of dried seeds of cacao (cocoa beans) supports an international market of approximately 3 million tons, with two-thirds being processed into cocoa powder and cocoa butter, and the remaining one-third used for cocoa liquor (the flavor and color component of chocolate) (Wood and Lass, 1985). Cocoa is the major export commodity of several countries in West Africa (68% of world production), including Ivory Coast, Cameroon, Nigeria, and Ghana. Other major cocoa exporters include Ecuador, Venezuela, Brazil, Panama, Costa Rica, Dominican Republic, Malaysia, and Indonesia. Worldwide, approximately 5–6 million small-holder farmers grow 95% of the world's production providing an important source of cash to otherwise primarily subsistence farmers. World cocoa export commerce is \$5 to \$6 billion/year and in the United States alone, the use of cocoa and cocoa butter in chocolate manufacturing, cosmetics, and other products drives an approximately \$70 billion dollar market providing over 60 000 jobs (Morais, 2005). In addition, US chocolate production also uses large amounts of sugar, nuts, and milk valued

at approximately \$3 billion per year in receipts to American farmers.

Cacao is grown in some of the world's most important biodiversity hotspots (Piasentin and Klare-Repnik, 2004). With a long life cycle, predominantly cultivated under shade trees, there are many environmental benefits of cacao cultivation such as watershed and soil conservation, provision of habitat for birds and other animals, and provision of buffering habitat for protected wild rainforest regions (Rice and Greenberg, 2003; Ruf and Zadi, 2003). With these benefits in mind development agencies such as United States Agency for International Development (USAID), Conservation International (CI), The World Wildlife Federation (WWF), and the World Cocoa Foundation have formed alliances to promote sustainable cacao production (Guyton *et al.*, 2003).

Overwhelmingly, plant pathogens present the major challenge to sustainable cacao farming throughout the world. It is estimated that pests and diseases reduce the potential crop by an estimated 810 000 t annually (30% of world production) and individual farm losses can approach 100% (Keane, 1992; Bowers *et al.*, 2001). In one example, Witches' broom disease resulted in a decrease of production in Southern Bahia, Brazil, from 300 000 t in 1989 to 130 000 t 10 years later, for an estimated loss of \$220 million each year (Pereira *et al.*, 1990). This caused a cascade of widespread social disruption among small-holder growers

including loss of land and home ownership. Widely dispersed cacao pathogens include several species of *Phytophthora* (Appiah *et al.*, 2003, 2004; Chowdappa *et al.*, 2003). *Phytophthora megakarya*, the most aggressive species, is reported to have entered Ivory Coast, the world's leading cocoa producer (Nyasse *et al.*, 2002; Opoku *et al.*, 2002; Appiah *et al.*, 2003; Risterucci *et al.*, 2003; Efombagn *et al.*, 2004). Other important diseases and pests include frosty pod in Central America (Evans *et al.*, 2003), the cocoa pod borer (CPB) in Asia (Day, 1986; Santoso *et al.*, 2004), and cocoa swollen shoot virus in West Africa (Hanna, 1954; Hervé *et al.*, 1991; Muller and Sackey, 2005).

The fields of cacao genetics, breeding, and biotechnology have been the subject of a number of relatively recent review articles (Bartley, 1994; Hughes and Ollennu, 1994; Bennett, 2003; Figueira and Alemanno, 2005; Guiltinan, 2007); two books (Dias, 2001; Bartley, 2005) and a conference proceedings (Eskes, 2005). Large genetic variation has been identified in wild populations throughout the Amazon, but this diversity has not yet been widely incorporated into cultivated varieties (Bartley, 2005). Conventional cacao breeding programs were started in the 1920s (Toxopeus, 1969). In the 1930s and 1940s, valuable germplasm was collected from the Amazon regions of Brazil, Ecuador, and Peru (Pound, 1940), and these accessions are maintained as live trees in present day germplasm banks (Lockwood and Gyamfi, 1979; Engels, 1981; Iwaro *et al.*, 2003). Cacao breeding is slow and only recently molecular markers have been used to identify quantitative trait loci (QTLs) to potentially speed up breeding programs (Lanaud *et al.*, 1996; Motilal *et al.*, 2000; Flament *et al.*, 2001; Clement *et al.*, 2003; Risterucci *et al.*, 2003; Queiroz *et al.*, 2003). The current genetic map contains approximately 465 markers, 268 of which are simple sequence repeats (SSRs) (Pugh *et al.*, 2004).

Important traits for cacao include yield efficiency, flavor characteristics, cocoa butter content (% seed lipid content) and quality (fatty acid saturation), tolerance to abiotic stress, and various horticultural traits such as precocity, rootstock/scion interactions, plant height, and stature. However, disease resistance is currently the primary trait targeted by cacao breeders. It is thought that most important cacao plant pathogens did not co-evolve with the species, making it highly unlikely that true

resistance genes will be available in the existing germplasm. For this reason, transgenesis holds an important potential to contribute to cacao genetic improvement. This review will cover the development of tissue culture-based regeneration and genetic transformation systems for cacao. A brief presentation of the legal and societal issues surrounding this technology follows.

2. DEVELOPMENT OF TRANSGENIC CACAO

2.1 Somatic Embryogenesis of Cacao: A Prerequisite for Development of an *Agrobacterium*-Mediated Genetic Transformation System

One of the first steps in developing a successful genetic transformation system for cacao was the development of a highly efficient protocol for *de novo* regeneration of plants from a wide variety of cacao genotypes. Research has been focused mainly on developing somatic embryogenesis (SE) systems from different plant organs and tissues. No success has been reported on the development of organogenesis-based regeneration systems for cacao, such as a leaf explant method. Early attempts reported on the initiation of cacao SE from immature zygotic embryo tissue (Esan, 1977; Pence *et al.*, 1979; Aguilar *et al.*, 1992), leaves (Litz, 1986), nucellus (Sondahl *et al.*, 1989; Chatelet *et al.*, 1992; Figueira and Janick, 1993), and floral explants, including petals and staminodes (Lopez-Baez *et al.*, 1993; Alemanno *et al.*, 1996; Alemanno *et al.*, 1997). However, all of these studies described partial success in producing somatic embryos from a small number of genotypes with no or low rates of embryo to plant conversion.

More recent studies have focused on optimizing the SE system for cacao using floral organ explants (staminodes and petals). The following section reviews the studies completed at The Pennsylvania State University concerning the development of a highly efficient system for somatic embryo-derived cacao plants from many different cacao genotypes (Li *et al.*, 1998; Traore, 2000; Maximova *et al.*, 2002, 2005). This system was consequently successfully utilized for *Agrobacterium*-mediated genetic transformation (Maximova *et al.*, 2003, 2006). It consists of

multiple steps/protocols that involve specific media formulations and periods of culture. The steps include: primary somatic embryogenesis (PSE; from staminode explants), secondary somatic embryogenesis (SSE; from somatic embryo explants), somatic embryo conversion to plants, and plant acclimation to greenhouse conditions. Detailed, complete protocols of the system were published by Maximova and co-workers in 2005 (Maximova *et al.*, 2005) and are available at <http://guiltinlab.cas.psu.edu/Research/Cocoa/protocols.htm>.

Here we present only the main findings along the developmental process.

The first report on PSE by this group was published by Li *et al.* (1998). The publication described the production of primary somatic embryos from 19 different cacao genotypes using staminodes as explants. The study built upon works published by others as reviewed above. Several hormone regimes were tested to increase embryogenic induction. The highest regeneration frequencies (percentage of regenerating explants) were recorded after supplementing primary callus growth medium (PCG) with 22.7 nM thidiazuron (TDZ) and 9 μ M 2,4-dichloro-phenoxyacetic acid (2,4-D). Another important factor for the success of this system was the substitution of the more traditionally used Murashige and Skoog (MS) salts with the Driver and Kuniyuki walnut basal salts (DKW) (Driver and Kuniyuki, 1984). It was found that MS media does not support cacao tissue culture and is nearly lethal to the cells. The study reported wide variation among the different genotypes evaluated in regard to the percentage of regenerating explants as well as the average number of embryos produced per explant. The percentages of regenerating explants varied from 0.8% to 100% and the average number of somatic embryos per explant ranged from 1 to 45.7. The genotype with the highest performance was PSU-Sca 6 with 100% regenerating explants and an average of 45.7 embryos per explant. The lowest regenerating genotype was EET400 with 0.8% regeneration rate and an average of one embryo per explant. It was obvious from the results that this protocol was most favorable for PSU-Sca 6 but there were no apparent correlations between the differences in the response relative to the three different major cacao groups—Forastero, Criollo, and Trinitario. Consequently, PSU-Sca 6

was selected as a potential candidate for future development of a transformation system.

A major increase in the efficiency above the method reported by Li *et al.* (1998) included the development of a protocol for secondary embryogenesis using cotyledon explants from primary somatic embryos (Maximova *et al.*, 2002). For initiation of SSE, cotyledon pieces (approximately 4 mm²) were cultured for 14 days on modified secondary callus growth medium (SCG) containing 2.4 μ M 2,4-D and 1.4 μ M 6-benzylaminopurine (BA) (Li *et al.*, 1998), followed by transfer and maintenance on hormone-free embryo development medium (ED) (Li *et al.*, 1998). The study presented strong evidence that the secondary embryogenesis process increased the multiplication rate of genotype PSU-Sca 6 by 30-fold compared to primary embryogenesis alone. Similar to primary embryogenesis, the response was variable among the genotypes evaluated. However, after a few primary embryos were regenerated from genotypes with low embryogenic potential, the secondary embryogenesis process assured the further multiplication of these genotypes. The comparison of the sizes of the primary and secondary embryos indicated that secondary embryos have significantly lower variation in size (10-fold). Additionally, the histological analysis of early stages of embryogenesis pointed toward a predominantly unicellular origin of SSEs compared to multicellular origin of PSEs. Considering all advantages of secondary embryogenesis the process was selected as the step in the regeneration system that would be suitable for co-cultivation with *Agrobacterium* and a basis for the development of a genetic transformation system (described in Section 2.3).

An important final step in the regeneration system was the development of protocols for conversion of the somatic embryos to plants and their acclimation to greenhouse conditions (Traore, 2000). The conversion procedure was first optimized for PSU-Sca 6 and later applied for other genotypes. The hormone-free embryo conversion medium (Li *et al.*, 1998) was supplemented with different basal salts formulations. These included MS basal salts, woody plant salts (WPM), and DKW salts. The highest percentages of converted embryos (77%) were recorded after culture on DKW and WPM basal salts. Supplementing DKW with additional 0.3 g

potassium nitrate and $2.5 \mu\text{M}$ the amino acids arginine, glycine, leucine, lysine, and tryptophan increased the conversion rate to 92%. In addition to the media composition, it was observed that the morphological characteristics of the mature embryos are important factors for the success of the conversion. Two different classes of embryos (I and II) were first described by Li *et al.* (1998) based on morphological appearance. Type I embryos displayed yellow translucent color and larger cotyledons compared to type II embryos that had ivory white color and small cotyledons. The conversion of type II embryos resulted in higher conversion rate to plants. Plants produced by this method were transplanted to soil in a greenhouse with 100% humidity and 70% shade (approximately $100 \mu\text{mol m}^{-2} \text{s}^{-1}$). Humidity was maintained by misting for 10 s every 15 min. After 4 weeks the misting was omitted and plants were successfully maintained to maturity at 60–65% humidity with 50% shade ($250\text{--}500 \mu\text{mol m}^{-2} \text{s}^{-1}$) (Maximova *et al.*, 2005). Plants produced by different genotypes are in the process of field evaluation in Saint Lucia, Ecuador, and Puerto Rico.

2.2 SE Research and Genetic Transformation Studies of Cacao at the Malaysian Cocoa Board, COCOA Biotech Center

Various explant sources (leaf, stem, young shoots, seed, flowers, etc.) from different commercial cocoa clones planted in Malaysia were evaluated for their potential for SE using previously published protocols (Aguilar *et al.*, 1992; Figueira and Janick, 1995; Alemanno *et al.*, 1996). From these, only seed, cotyledon tissue, and flower organs regenerated somatic embryos (T.C. Lock, unpublished data). Young cotyledon tissues (white to pale purple color) were more reactive compared to older cotyledon tissues (T.C. Lock, unpublished data). Although somatic embryos were produced from cotyledons, this source was not suitable for clonal propagation due to the fact that cotyledon tissue is a product of fertilization and is genetically different from the source materials. Further experiments were conducted with flower parts—anther filaments, staminodes, and petals (Tan and Furtek, 2003). Similar to the results reported by Li *et al.* (1998), the best regeneration

was recorded for staminode tissues (Figure 1). The genotype of cocoa was also an important factor for the success of embryogenesis as genotype-specific variations in the response were observed. Additionally, the time of the year when flowers were collected from the field and introduced in culture affects the embryo production (T.C. Lock, unpublished data). It was observed that after occurrence of a distinct dry period followed by a wet season, floral tissues performed better during SE. However, there is no actual data recorded that correlate the climatic conditions with embryogenesis rate and future experiments need to be conducted to verify these observations.

For induction of PSE, unopened flower buds (4–6 mm in length) were collected from the field and rinsed with tap water. The flowers were then sterilized in 70% ethanol for 5 min followed by 20 min in 10% commercial bleach (5.25% (v/v) sodium hypochlorite) and 0.10% sodium dodecylsulfate (SDS) solution, and 20 min in 1% bleach and 0.10% SDS solution. Buds were rinsed three times for 5 min in sterile reverse osmosis water. Staminodes were dissected in sterile conditions and cultured on somatic embryo induction medium (MIM41n). MIM41n consisted of DKW basal salt (Duchefa, Biochemie BV, The Netherlands), 20 g l^{-1} glucose, MS vitamins, 2 mg l^{-1} of 2,4-D, 0.1 g l^{-1} N^6 -[2-isopentenyl]adenine (2-iP), 500 mg l^{-1} glutamine, and 2 g l^{-1} Phytigel (Sigma), pH 5.8. Calli were formed after 2–3 weeks of culture on MIM41n media (Figure 1b). After 4–8 weeks, the calli were transferred to embryo differentiation media (MEM22a) consisting of DKW basal salts, MS vitamins, 50 mg l^{-1} and 2 g l^{-1} Phytigel, pH 5.5. Newly formed somatic embryos (Figure 1c) were separated from the calli and subcultured onto differentiation media for another 4–6 weeks. Secondary embryos (Figure 1d) were formed spontaneously on MEM22a medium and after culture on MEM22a supplemented with 0.01 mg l^{-1} 2-iP and 0.01 mg l^{-1} kinetin. The mature somatic embryos produced were approximately 40 mm long with distinct shoot and root apices. These were introduced into conversion media (MGM) consisting of one-fifth strength DKW basal salts, 5 g l^{-1} sucrose, 10 g l^{-1} glucose, 100 mg l^{-1} myo-inositol, 2 mg l^{-1} glycine, 2.2 g l^{-1} Phytigel (Sigma), pH 5.8. MGM medium was dispensed onto 250 ml glass jars

Figure 1 Somatic embryogenesis of *Theobroma cacao*. (a) Unopened flower bud, scale bar = 1.6 mm, (b) callus from staminode, scale bar = 1 mm, (c) primary somatic embryos from callus, scale bar = 2 mm, (d) secondary somatic embryos from primary embryo, scale bar = 0.9 mm, (e) plantlet from somatic embryo, scale bar = 10 mm, (f) plantlets in light culture room, scale bar = 5 cm, (g) cytological analysis of root tips from plantlet, scale bar = 10 mm, (h) somatic embryo derived plants established under *ex vitro* conditions, scale bar = 21 cm

(Biocraft, Singapore) and covered with Suncaps (Sigma) for ventilation. The conversion cultures were kept under light (16 h photoperiod, daylight fluorescent tubes, $25 \text{ mmol m}^{-2} \text{ s}^{-1}$) at $25 \pm 2^\circ \text{C}$ (Tan and Furtek, 2003). Roots usually appear after 3 weeks on conversion media followed by leaf development (approximately 4 to 8 weeks on conversion media). Once a healthy root system and dark green leaves were developed, the plantlets were transferred to *ex vitro* conditions (Figures 1e and f). Embryogenesis was most successful for genotypes QH1560, KKM19, PBC137, and KKM4 (commercial clones in Malaysia). The percentages of embryos producing explants (0% to 50%) varied greatly with the season and age of the source plants, and the genotypes. Between 5% and 15% of the somatic embryos were converted to plantlets.

To test for mutations and somaclonal variation as a result of the SE, SE-derived plants were analyzed and compared to the explant source plants by molecular fingerprinting and morphological characterization. Two- to three-year-old somatic embryo-derived plants and their mother plants were fingerprinted using 39 different microsatellite

markers (T.C. Lock, unpublished data). Genomic DNA was isolated from young, fully expanded leaves from somatic embryo-derived plants and mother plants using DNeasy 96 Plant kit (Qiagen). Polymerase chain reaction (PCR) amplification of the target sequences was performed using Applied Biosystems 96-Well GeneAmp[®] PCR System 9700. Each reaction contained 1U of *Taq* polymerase, 10 ng cocoa DNA, 0.2 mM dNTP mix, 2 mM MgCl_2 , $1 \times$ reaction buffer, and 2 pmol of fluorescently labeled primers in total volume of 20 μl . The PCR conditions applied were: 94°C for 4 min, followed by 30 cycles of 30 s at 94°C , 30 s at 50°C , and 1 min at 72°C . One to 10 dilutions were made from each PCR product and 1 μl from each sample was mixed with 1 μl ROX in an individual tube. The samples were denatured at 95°C for 3–5 min, cooled on ice, and fractionated by capillary electrophoresis using Amersham MegaBACE 500 analysis system. The SSR profiles were analyzed using GENOTYPER software (Applied Biosystems, Foster City, CA). The genotyping analysis demonstrated no differences between the somatic embryo-derived plants and the flower source plants. Additional cytological

analysis of root tips from the somatic embryo-derived plants and the source plants revealed an equal chromosome count of $2n = 20$ (Figure 1g) (T.C. Lock, unpublished data). Preliminary morphological examination of leaves and flowers also showed no differences from the mother plants (Figure 1h).

Agrobacterium-mediated transformation experiments were conducted with untreated staminode tissue, 3-week-old calli from staminodes, zygotic and somatic embryo pieces. The *Agrobacterium* strain used in the transformation was AGL1 carrying vector pGPTV-Kan: contains neomycin Phosphotransferase II (*nptII*) (kanamycin resistance) gene and β -glucuronidase (*GUS*) reporter gene (Becker *et al.*, 1992). The *Agrobacterium* was incubated for 48 h at room temperature (approximately 28 °C) in 523 medium with 50 mg l⁻¹ rifampicin, 50 mg l⁻¹ tetracycline, 50 mg l⁻¹ carbenicillin, and 100 μ M acetosyringone. The calli were inoculated with the *Agrobacterium* suspension (1.0 OD at 600 nm) for 30 s, blotted on sterile paper towels, and were then cultured on MEM22a medium with mg l⁻¹ cefotaxime and 250 mg l⁻¹ augmentin for 7 days. Subsequently, the calli were transferred to MEM22a medium with 250 mg l⁻¹ cefotaxime, 250 mg l⁻¹ augmentin, and 100 mg l⁻¹ paromomycin for selection. After approximately 5 weeks, the calli and newly developed somatic embryos were histochemically stained for GUS expression. The blue color observed indicated the development of putatively transformed calli (Figure 2a). Additionally, the formation of chimeric somatic embryos was observed (Figure 2b) (Tan *et al.*, 2001), which could be due to the possible multicellular origin of the primary embryos (Maximova *et al.*, 2002). Similar results were observed after transformation of callus derived from zygotic and somatic embryo

pieces (data not shown). Additionally, biolistics transformation was carried out using pVDH65 and 3-week-old staminode calli using BioRad PDS-1000/He system. The vector construct used included a triple cauliflower mosaic virus (CaMV) 35S promoter fused to a *GUS* gene (Tan *et al.*, 1999). The GUS histochemical staining resulted in the formation of approximately 40–50 blue spots per 3 mm² of callus as an indicator of transient expression. The number of blue spots observed decreased over time and no differentiation of transgenic somatic embryos was recorded.

2.3 *Agrobacterium*-Mediated Cacao Transformation: Protocol Development and Expression of Genes with Potential Agronomic Importance

2.3.1 Genetic transformation protocol development

Prior to year 2000 only one research publication could be found reporting attempts at cacao transformation. In this study, cacao leaf strips were inoculated with *Agrobacterium tumefaciens* carrying a vector with GUS and *nptII* genes (Sain *et al.*, 1994). The experiment resulted in the formation of transformed callus cells, but no transgenic plants were regenerated. In 1996, the Pennsylvania State University Cacao group began a program dedicated to the development of a reliable genetic transformation protocol based on the recently established SE tissue culture system described above. The development and optimization studies included evaluations of different vectors and reporter genes, various selective antibiotics, different somatic embryo tissues,

Figure 2 Genetic transformation of *Theobroma cacao* L. (a) Partially transformed callus, scale bar = 0.9 mm, (b) putative transformed callus, scale bar = 0.9 mm, (c) putatively transformed somatic embryos, scale bar = 0.8 mm, (d) partially transformed somatic embryo, scale bar = 0.7 mm

and the potentials of particle bombardment and *Agrobacterium*-mediated methods (Guiltinan and Maximova, 2000; Traore, 2000; Antunez de Mayolo *et al.*, 2003; Maximova *et al.*, 2003). To assess the potential of the biolistic method, cells grown in suspension cultures and somatic embryo cotyledon tissues were bombarded with 1 μm gold particles in a helium-driven PDS-100/He system (Traore, 2000). The gold particles were coated with pBI221 DNA containing *GUS* and *nptII* genes (De Block *et al.*, 1984). Three days after treatment *GUS* expression was evaluated and large numbers of blue spots were observed in the callus and the cotyledon tissue. However, no embryos were ever regenerated from these experiments (Traore, 2000). This method is considered a useful and quick method to check for construct expression in cacao cells prior to use in further attempts at stable transformation, but highlighted the need for improvement of cacao regeneration systems.

Thus, after several years of optimization of the SE system, attempts were made for *Agrobacterium*-mediated transformations using somatic embryos as explant sources. A major contribution to the development of the protocol was the utilization of the green fluorescent protein (GFP) reporter gene (Chalfie *et al.*, 1994). The ability to observe green fluorescence as an indication of transformation events within 48 h after *Agrobacterium* inoculation greatly increased the early screening capabilities (Maximova *et al.*, 2003). Additionally, the incorporation of GFP allowed the nondestructive observation of the explants throughout the entire culture period including the detection of the transgenic somatic embryos that were regenerated in low frequencies. This permitted relatively rapid optimizations of the many variables in the protocol.

Another important variable optimized was the selective antibiotic used in the regeneration medium. To select the best antibiotic for *nptII* resistance of transgenic cacao cells, the effect of different types of aminoglycoside antibiotics including paromomycin, neomycin, kanamycin, and geneticin at concentrations of 125, 150, 175, and 200 mg l^{-1} was evaluated. The number of GFP expressing explants and the total number of GFP expressing areas were recorded at 1, 2, and 3 weeks after bacterial inoculation. The highest percentage of expressing explants (49%) and the highest total number of GFP areas (64)

was observed after application of geneticin at 125 mg l^{-1} (S.M. Maximova and M.J. Guiltinan, unpublished data). Thus, this antibiotic was selected for further experiments subsequently adjusted to a concentration of 50 mg l^{-1} for 2 weeks after inoculation (Maximova *et al.*, 2003). A similar approach was exploited for selection of the *Agrobacterium* counter-selection antibiotic (Antunez de Mayolo *et al.*, 2003). For this study, it was necessary to evaluate the effect of the applied antibiotics on SE and in eliminating *Agrobacterium* in the regeneration culture after the initial co-cultivation period of 48 h. Different antibiotics were supplemented to the regeneration medium in four different concentrations (100, 150, 200, and 300 mg l^{-1}). The antibiotics included: from the cephalosporin class—cefotaxime and moxalactam, and from the penicillin class—amoxicillin and carbenicillin. The percentage of explants lost to *Agrobacterium* overgrowth was evaluated in addition to the effect of the antibiotic type and concentration to the average number of embryos produced in the absence of *Agrobacterium* inoculation. As a result moxalactam at 200 mg l^{-1} was selected as the most promising antibiotic that assured that no explants were lost to bacterial overgrowth and in fact increased the average number of primary and secondary embryos produced per explant by threefold compared to no antibiotic controls (Antunez de Mayolo *et al.*, 2003). This increase of regeneration efficiency could be due to a possible auxin response of the tissue to one of the several breakdown components of moxalactam, phenylacetic acid, which is a naturally occurring auxin (Webber and Yoshida, 1979).

As a result of combining high efficiency SE with *Agrobacterium*-mediated transformation using a GFP reporter gene, transgenic *T. cacao* plants were obtained and grown to maturity (Maximova *et al.*, 2003). With optimization of the protocol, the numbers of transgenic plants recovered from a single experiment increased from one in early experiments to a high of 10 independent transgenic plants. All binary vectors utilized included the Bin19 backbone (Bevan, 1984), *nptII* (De Block *et al.*, 1984) and EGFP (Clontech, Palo Alto, CA) genes both under the control of E12- Ω constitutive promoter, a very highly expressed derivative of CaMV 35S promoter (Mitsuhara *et al.*, 1996). Additionally, pGH00.0131 included

Tobacco Matrix Attachment regions (MARs) (Spiker and Thompson, 1996) flanking the transfer DNA (T-DNA) region. The presence of the MARs contributed to increased GFP fluorescence in primary transgenics and stable and uniform GFP expression among the tertiary somatic embryos propagated from the cotyledons of primary transgenics (Maximova *et al.*, 2003). The physiological and morphological observations of the transgenic cacao plants produced indicated that genetic transformation events and transgene expression did not cause any detectable pleiotropic phenotypic changes. On occasion gene silencing was observed during reiterative embryogenic multiplication (S.M. Maximova and M.J. Guiltinan, unpublished data). Many mature somatic embryos were converted to plants and transferred to greenhouse conditions for further evaluation. Ten transgenic plants from the first established transgenic lines were closely observed during a period of 5 months and their growth parameters were recorded and compared to ten nontransgenic somatic embryo-derived control plants (Maximova *et al.*, 2003). The parameters measured were height, stem diameter, number of leaves, and total leaf area. No significant differences were recorded among the plants for any of the parameters. After approximately 1.5 years of growth in the greenhouse, the transgenic plants developed flowers exhibiting bright GFP expression. The flowers were pollinated with pollen from nontransgenic *T. cacao* genotype Catongo. The pods produced from this crosses exhibited high levels of GFP fluorescence of all maternal pod tissues including pod surface, exocarp, placental tissues, and seed coat. Very high levels of GFP fluorescence were observed in the cotyledons and the embryos of the transgenic seeds. The GFP gene in the T₁ generation from several of the transgenic plants segregated as a single locus insertion (1:1 segregation ratio).

2.3.2 Expression of cacao *TcChi1* gene in transgenic cacao

As discussed in the introduction, cacao pests and diseases are major constraints to sustainable cacao production, and many of these are fungal pathogens. With this in mind, the first gene with potential agronomic importance that was

introduced into cacao was a class I chitinase gene (*TcChi1*), encoding a potential antifungal protein (Maximova *et al.*, 2006). The *TcChi1* gene isolated from *T. cacao* encodes an endochitinase protein (NCBI accession U30324 (Snyder, 1994; Snyder-Leiby and Furtek, 1995)). The gene/protein belongs to the pathogenesis-related (PR) protein family and it was demonstrated to be expressed in cacao fruit in response to fungal elicitor treatment (Snyder-Leiby and Furtek, 1995). As a test of its putative function in pathogen resistance, it was hypothesized that the ectopic overexpression of this gene in cacao would contribute to increased resistance to fungal pathogens. The coding sequence of the chitinase gene was placed under the control of the highly expressed constitutive E12- Ω promoter (Mitsuhara *et al.*, 1996), the same used to drive the EGFP and *nptII* genes as described above. The gene was introduced into cacao via the SE co-cultivation system described above. Transgenic embryos were produced and converted to plants (Maximova *et al.*, 2003). Clonally propagated plants from nine transgenic lines were characterized for transgene integration and expression, and *in vitro* and *in vivo* chitinase activities were measured (Maximova *et al.*, 2006).

Southern genomic DNA blot analysis revealed multiple transgene insertion sites in eight of the lines, and one line with a single insertion. Expression of the *TcChi1* transgene was verified by Northern blot (Maximova *et al.*, 2006) and by quantitative real-time reverse transcription polymerase chain reaction (Q-PCR) analysis. For Q-PCR total leaf RNA was extracted from control PSU-Sca6 plants, three chitinase transgenic lines (T44.1, T56.2, and T61.7), and from one GFP transgenic control line (T-31-GFP) (Maximova *et al.*, 2006). RNA (400 ng) from each sample (three individual samples per transgenic line) was treated with DNase 1 (0.2 units) (#2222, Ambion, Austin, TX) in 20 μ l total reaction volume with 60 ng of yeast tRNA (Invitrogen, Carlsbad, CA) by the manufacturer's instructions. The reactions were incubated for 30 min at 37 °C, then for 5 min at 65 °C, and immediately placed on ice. The DNase treated RNA (50 ng) was added to High Capacity cDNA (complementary DNA) Archive Kit mix (#4322171, Applied Biosystems, Foster City, CA) to a final volume of 20 μ l and the reverse transcription reaction was performed by the manufacturer's instructions.

Gene specific primers were synthesized at the Penn State Nucleic Acid Facility with a MerMade12 automated DNA synthesizer (Bioautomation, Plano TX). Gene specific fluorescent probes were synthesized by Biosearch Technologies (Novato, CA). The fluorescent label used at the 5' end of all cacao gene probes was 6-carboxyfluorescein (6-FAM) and quencher at the 3' end of all gene probes was BHQ1 (Biosearch). The total volume of the PCR reaction was 25 μ l and the mix included; 5 μ l of cDNA (~12.5 ng), 12.5 μ l 2 \times TaqMan[®] Universal Master Mix (#4304437, Applied Biosystems, Foster City, CA), 400 nmoles of each primer, and 200 nmoles of probe. The PCR reactions were run in 96 well thin-walled PCR plates in an Applied Biosystems 7300 Q-PCR system (Foster City, CA) with the following reaction conditions: 2 min at 50 °C, 10 min at 95 °C, followed by 40 cycles of 15 s at 95 °C and 1 min at 60 °C. Each sample was amplified in triplicate and the results were averaged. In addition to the *TcChi1* transgene, the expression of four endogenous pathogenesis related (PR) genes in the control and transgenic lines were also evaluated. These genes were selected based on previous results that indicated their involvement in defense responses in cacao plants induced with chemical elicitors (Verica *et al.*, 2004). The genes included: two additional PR3 chitinases genes—Class 4 and Class 7; PR4-Osmotin; PR6-Type I proteinase inhibitorlike protein; and NPR1—a potential key regulator in the signal transduction pathway that leads to systemic acquired resistance. The mean expression of two cacao house keeping control genes, *actin* and *ubiquitin*, were used to normalize the data. Amplification efficiencies of all target and reference genes were calculated from the slopes of the dilution curves for each sample ($E = 10^{(-1/\text{slope})} - 1$) (Bustin, 2004). Average efficiency for each gene was then calculated and used for efficiency data correction. The data normalization, efficiency correction, statistical randomization test, and relative transgenic/control nontransgenic expression ratios were computed using REST software (Pfaffl *et al.*, 2002). Ratios (fold difference) with *p*-values less than 0.05 were considered significant (Table 1).

The results from the Q-PCR analysis indicated a large increase in *TcChi1* expression in all lines containing the transgene (Table 1). The fold difference compared to the nontransgenic

Table 1 Quantitative real-time reverse transcription polymerase chain reaction analysis (Q-PCR) of gene expression of *TcChi1* transgene and selected pathogenesis related genes. Total RNA was isolated from control PSU-Sca6 plants, transgenic line T31-GFP (expressing *EGFP* and *hptII* only), and three different transgenic lines containing the *TcChi1* gene. Differences in gene expression between the transgenic and nontransgenic tissues are represented as relative expression ratios (fold difference). The ratios were calculated using REST software (Pfaffl *et al.*, 2002) based on Q-PCR efficiencies and the mean crossing point (CP) values of the samples from individual transgenic line versus the mean CP values for PSU-Sca6 control nontransgenic samples. Ratios with *p*-values less than 0.05 were considered significant and listed in the table. When the transgenic samples were not significantly different, they are recorded as not significant (Ns)

Gene name	T31-GFP	T44.1	T56.2	T61.7
<i>TcChi1</i>	Ns	1,555.5	5,053.6	8.8
<i>TcChi4</i>	Ns	Ns	2.2	Ns
<i>TcChi7</i>	Ns	-1.7	-1.5	-1.9
<i>TcNPR1</i>	Ns	Ns	Ns	Ns
<i>TcPR6</i>	Ns	Ns	Ns	Ns

samples varied from 8.8-fold for line T61.7 to 5053.6-fold for the highest expressing line T56.2. Line T56.2 also demonstrated a 2.2-fold increase in *TcChi4*. Interestingly, a down-regulation of between 1.5- to 1.9-fold was observed for the *TcChi7* gene in all lines overexpressing *TcChi1*. The *in vitro* endochitinase protein activity assay also detected significant increases of chitinase activity in all *TcChi1* transgenic lines compared to the control T31-GFP and nontransgenic lines (Maximova *et al.*, 2002). The levels of chitinase activity in the three transgenic lines correlated well with the expression levels of the transgene: T61 had the lowest protein activity, followed by T44 with intermediate activity and T56 with the highest activity (Maximova *et al.*, 2006). The level of chitinase activity also corresponded well with the *in vivo* antifungal activity against *Colletotrichum gloeosporioides*, a pathogen of economic importance for cacao in India and Venezuela. To test the antifungal activity *in vivo*, excised cacao leaves were challenged with spores from *C. gloeosporioides* (Maximova *et al.*, 2006). The lines with the highest mRNA levels and the highest *in vitro* chitinase activity were better able to suppress the development of the fungus and formed smaller necrotic lesions compared to the lines with lower *in vitro* chitinase activity and the control nontransgenic plants. This study

demonstrated the utility of the transformation system as a tool for gene functional analysis and supports a functional role of the cacao *TcChl* gene in pathogen resistance in cacao. While by itself, overexpression of this gene is unlikely to confer high level fungal pathogen resistance, it is possible that combined with other resistance genes via breeding, and pest management strategies, it could contribute to an integrated approach for enhanced pathogen resistance.

2.3.3 Biotechnology for CPB resistance in cocoa

Conopomorpha cramerella, the CPB is one of the most important pests of cacao. Currently CPB affects almost all cocoa producing provinces in Indonesia. By 2000, CPB had infested 60 000 ha, inflicting losses of \$40 million per year (ICCO, 2006). Losses in cocoa yield depend on the age of the infested pods and the degree of infestation. The youngest pods are most susceptible to infection, and with increase in the insect pressure it was estimated that the losses could reach 93% on the individual plantations (Lumsden, 2003). In 2006, an outbreak of CPB was also reported in Papua New Guinea where according to a US State Department report, cacao represents the second largest export product (Merrett, 2006). From January to May 2006, CPB caused a 21% decrease in cacao export of Papua New Guinea compared to 2005. Methods for CPB control include: cultural practices, application of pesticides, biocontrol, use of resistant/tolerant planting materials, and use of pheromones. The effectiveness of any of these methods is hindered due to the fact that the CPB larvae are protected inside the cocoa pod almost half of their life cycle. The selection and breeding efforts for resistance to CPB are mainly directed toward plants with improved physical characteristics of the pod. These include hardness and thickness of sclerotic layer, husk thickness and smoothness of pod surface (Lumsden, 2003; Teh *et al.*, 2006). Although a few clones have been identified as moderately resistant to CPB, in general cacao breeding is a long and slow process and the introduction of new varieties is especially difficult considering the small-holder production systems in the developing countries. Thus, engineering resistance to CPB

in transgenic plants could potentially benefit the cacao producers.

The potential candidate genes are those encoding for the production of *Bacillus thuringiensis* toxins (*Bt*). *Bt*-toxins are natural proteins with insecticidal activity against lepidopteran insects and are also considered harmless to humans and most higher organisms (Schnepf *et al.*, 1998). Different *Bt* toxins have been evaluated for their activity against CPB larvae (Santoso *et al.*, 2004). Twelve different purified CryI class *Bt* toxins were added to CPB artificial diet and fed to CPB larvae. The larvae mortality was observed every day for 3 days. Application of a single dose of 100 ng cm⁻² of four different *Bt* toxins resulted in approximately 20–50% larvae mortality.

With the goal to produce transgenic cacao including *Bt* toxin genes with potential resistance to CPB, a collaborative research project was established between the Plant Research International, Wageningen, The Netherlands and the Indonesian Biotechnology Research Institute of Estate Crops, Bogor, Indonesia (Chaidamsari, 2005). The *Bt* toxin gene selected was SN19 hybrid gene encoding a protein consisting of domains I and III of *CryI_{Ab}* and domain II of *CryII_a* (Naimov *et al.*, 2001). The sequences of domains I and III of the gene were modified by PCR site directed mutagenesis to increase its expression in plants (Chaidamsari, 2005). Binary vectors pSN48, pTC4, pTC9, and pTC12 contained different versions of the gene containing modifications of one, two, or all three domains of the gene. Vector pTC13 included a control nonmodified gene *SN19*. The constructs were first introduced in transgenic *Arabidopsis thaliana* ecotype WS as a model system to rapidly evaluate the expression and effectiveness of the *Bt* transgenes. Larvae of two insect species, *Pieris rapae* and *Plutella xylostella*, were fed with leaves from transgenic plants containing the various constructs and larvae mortality was observed. Depending on the vector, between 25% and 86% of the plants evaluated caused 100% larvae mortality for both the insect species. The largest percentage of plants causing 100% mortality was recorded for pSN48 containing synthetic domains I and III. The analysis of protein content of these plants indicated that SN48 constituted 0.01–0.1% of the total soluble protein.

Transformation vectors pMH58 and pMH59 were constructed for transformation of cacao.

Vector pMH58 contained the *SN19* gene with synthetic domains I and III encoding fragments (comparable with pSN48) and vector pMH59 contained modifications of all the three domains of *SN19*. Both genes were placed under the control of the CaMV 35S promoter. *Agrobacterium* transformations were performed with somatic embryos derived from staminodes of clone Sca6. After recovery of transgenic somatic embryos, secondary embryos were transferred to PCG medium (Li *et al.*, 1998) to allow callus formation. Calli were maintained on the same medium for 5 months and *Bt* protein levels evaluated by immunoassay. Preliminary data demonstrated that calli transformed with pMH58 showed the highest protein content/expression levels, ranging from 0% to 1.4% of total soluble protein, while pMH59 ranged from 0% to 0.2% (Chaidamsari, 2005).

Because CPB primarily affects the pods and specifically enters through the pod wall, it would be advantageous to utilize promoters to drive *Bt* expression only in the pod wall. Thus as part of this study, Chaidamsari (2005) also identified the *TcLea5* gene as primarily expressed in the inner pod wall and somewhat in the outer pod wall but not in pulp, beans, and leaves. The putative *TcLea5* promoter was characterized and the promoter activity was verified in tomato as a model species. Further production and evaluation of transgenic plants producing *Bt* toxins under tissue-specific promoters are necessary to demonstrate the success and potential application of this technology for cacao.

3. FUTURE ROAD MAP

The future of transgenic cacao is currently uncertain. The use of this system for studying gene expression and protein function has been demonstrated but with the current protocols, the efficiency and expense of this method is prohibitive to most laboratories. Heterologous model plant systems such as *Arabidopsis* and tomato may prove to be much better species for the study of cacao gene function. However, precise investigations of molecular interactions may be limited in heterologous expression systems due to subtle differences between species. Therefore in the future, advanced studies of cacao gene function will ultimately require improved and more efficient

cacao transformation methods. Higher transformation efficiencies, faster regeneration methods, and tissue-specific and regulated promoters are all required.

In addition to its utility as a method to study gene function in cacao, transformation holds a huge potential to contribute to the improvement of insect- and disease-resistant lines of cacao or for development of other desirable traits such as drought, cold, and herbicide resistance, etc. However, before commercial lines of cacao with desired traits are even considered, the societal, legal, and ethical issues involved must be carefully thought-out. By far, the largest impediment to the development of these technologies and to the application of genetic engineering for cacao improvement is the public perception of the potential ethical and biosafety issues surrounding this field. The perception of chocolate as a luxury food, and its association with children makes cacao biotechnology especially sensitive to public scrutiny. Because of this, research to develop this technology for cacao has suffered from lack of funding, and thus has lagged well behind other plant species such as corn, rice, and soybean. Furthermore, because cacao is grown in the developing countries, issues surrounding IP rights, farmer rights, and biosafety protocols in these countries are currently highly variable and not clear in many cases.

However, fact remains that cacao germplasm does not contain resistance genes for many of the opportunistic pathogens that inflict huge losses to farmers in many countries where cacao has been introduced. Integrated pest management approaches are being employed to address these problems; however, implementation of these methods requires educating millions of poor farmers who may not have the time or resources to apply them. Clearly, genetically encoded traits such as those made possible with transgenesis would be a powerful tool to help solve the problems facing cacao farmers today. The paradox between public hesitance and farmers' needs will play out in the future as cacao pathogens continue to spread from country to country and new pathogens invade the cacao fields.

In the future, native gene transformation (transformation with gene sequences originating only from the same plant species) and gene targeting methods need to be developed which

will eliminate many of the concerns regarding the precision and safety of transgenic technologies. These breakthroughs will be as important for cacao as for any other plant species. Manipulation of the key transcription factors that regulate plant growth and development as well as responses to biotic and abiotic stress will lead to novel approaches to crop improvement, but a much deeper understanding of the basic mechanisms of plant molecular biology is required before this can be adapted to cacao.

ACKNOWLEDGMENTS

The authors would like to thank Marna Yandeau-Nelson and Joseph Verica for their careful reading of this manuscript and helpful suggestions.

Tea

Tapan K. Mondal

*Department of Plantation Crops and Processing, Uttar Banga Krishi Viswavidyalaya,
West Bengal, India*

1. INTRODUCTION

Tea (*Camellia sinensis* L.) belongs to the family Theaceae. It is the oldest nonalcoholic caffeine-containing beverage crop of the world. The Chinese were the first to use tea as a medicinal drink, later as a beverage, and they have been doing so for the past 5000 years (Eden, 1958). The cultivated taxa of tea comprise three main natural hybrids: *C. sinensis* (L.) O. Kuntze or China type, *Camellia assamica* (Masters) or Assam type, and *C. assamica* subsp. *lasiocalyx* (Planchon ex Watt.) or Cambod or southern type. Tea is an evergreen, perennial, cross-pollinated plant and grows naturally as tall as 15 m. However, under cultivated condition, the bush height of 60–100 cm is maintained for harvesting the young leaves, which continues even more than 100 years. Flowers are white in color and borne singly or in pairs at the axils. Fruits are green in color with two to three seeds and start bearing within 5–6 years after planting.

1.1 History

Tea plants are believed to have been discovered accidentally by the Chinese legendary emperor Sheng Nong around 2737 BC. As soon as its medicinal value began to be attributed to China, a demand for supplies of tea sprang up, which resulted in cultivation of tea plant in Sichuan province about 3000 years ago. Subsequently, the

knowledge of tea cultivation spread everywhere with fine arts of Buddhism. Though, in India, wild tea plant was discovered by C.A. Bruce in Assam during 1823, seeds were brought by G.J. Gordon from China in 1836 for establishing a commercial garden. Later C.A. Bruce was appointed as the superintendent of the government tea plantation, who took active interest in the indigenous tea plants. Soon commercial interests moved on and the world's first privately owned tea company, the Assam Tea Company, was established on February 12, 1839, with the directives from the British Parliament. This was the beginning of the present-day tea industry in India.

1.2 Origin and Distribution

Southeast Asia is the original home for tea. According to Wight (1962), primary center of origin of tea is considered around the point of intersection of latitude 29° N and longitude 98° E near the source of the river “Irrawaddy”; the point of confluence where lands of Assam, north Burma, southwest China, and Tibet meet. The secondary center of origin is considered to be located in southeast China, Indochina, Mizoram, and Meghalaya (Kingdon-Ward, 1950). The above areas are, therefore, considered to be the zone of origin and dispersion of the genus *Camellia* as a whole (Sealy, 1958). However, presently tea is grown within the latitudinal range of 45° N to 34° S.

Tea was introduced into Japan from China in the early part of the 8th century. From Japan, tea cultivation extended to Indonesia during the 17th century. In Sri Lanka, tea was first planted in 1839 when seeds were brought from Calcutta. In USSR, tea cultivation started when seeds were imported from China toward the end of the last century. Later, from USSR, seeds were exported to Turkey in the year 1939–1940. In Europe, tea was introduced during 1740 by the East India Company's Captain Goff, but the plants that were planted in the Royal Botanical Garden at Kew in England could not survive (Sealy, 1958) and the first successful introduction was achieved by a British merchant and naturalist John Ellis in 1768 (Aiton, 1789; Booth, 1830). From there tea cultivation spread to the African countries at the end of the 19th century. Presently, it is cultivated in more than 52 countries worldwide.

1.3 Botanical Description

A summary of morphological characters of cultivated tea plants is given below (Barua, 1963).

1.3.1 *C. sinensis*

The plant is a 1–3-m-tall shrub with many stems arising from the base of the plant near the ground. The relatively small, thick, and leathery leaves have stomata that appear to be sunken in the lamina. Short and stout petioles give the leaf an erect pose and are usually three to seven in number. The flowers that are borne singly or in pairs in the axils and have 6–10-mm-long pedicels with two to three subopposite scar. Flowers are characterized by seven to eight cup-shaped, 1.5–2.0 cm long, and broad-oval to suborbicular petals with about three to five styles that are generally free for greater part of their length but occasionally free up to the base of the ovary. The capsules have one, two, or three locules containing one to three nearly spherical seeds of about 10–15 mm in diameter.

1.3.2 *C. assamica* (Masters)

It is a 10–15-m-high tree with a trunk and robust branching system. The relatively large, thin,

glossy leaves with more or less acuminate apex have distinct marginal veins and broadly elliptic leaf blades that are usually 8–20 cm long and 3.5–7.5 cm wide. A single or paired pedicellate flower has smooth and green scars of three bracteoles, numerous stamens, five to six persistent sepals, and seven to eight white petals.

1.3.3 *C. assamica* subsp. *lasiocalyx* (Planch. ex Watt.)

The plant is 6–10-m-tall, upright tree with several, almost equally developed, branches and more or less erect, glossy, light green to coppery-yellow or pinkish red leaves, the size of which is intermediate between *C. sinensis* and *C. assamica*. Although flowers are more or less similar to the Assam type yet, they have four or more bracteoles, three to four ovules with five locules, and three to five styles that are free up to half the length.

1.4 Taxonomic Position

In 1689, a Dutch physician and botanist Andre Cley published in Latin a work mentioning the tea plant as “tsumacky”, which means “tsubaki” in Japanese. Later, in 1702 James Petiver and in 1712 Engelbert Kaempfer described the same name. In 1753, Linnaeus used Kaempfer's illustrations to describe the China plant under the name *Camellia tsubaki* and subsequently it appeared in his book *Species Plantarum Volume 1* as *Thea sinensis*. The modern generic name *Camellia* was dedicated to Moravian Jesuit Kamel, a German missionary stationed in the Philippines, who wrote about the plant, found in Asia during the later half of the 17th century. Moreover, tea was known under various botanical names, such as *Camellia thea* Dyer, and also *T. sinensis*, *Thea Bohea*, or *Thea viridis* (Eden, 1958).

Thus in 1935, in order to avoid confusion, the International Botanical Congress held at Amsterdam decided to merge the two genera *Thea* and *Camellia* into a single genus, i.e., *Camellia*. The committee decided *C. sinensis* (L.) to be the correct name of the tea plant. Technically, *C. sinensis* (L.) O. Kuntze is considered to be the full name of tea plant. The family Theaceae, tribe Gordonieae, comprises 16–25 genera with more

than 325 species. The genus *Camellia* of which tea is a member belongs to the family Theaceae, tribe Gordoneae, along with eight other genera, among which *Camellia* is the largest. Sealy (1958) listed 82 species within the genus *Camellia* and 16 other imperfectly known species whose status was not decided.

1.5 Genome Size and Diversity

The genome size in terms of 4C DNA amount for *C. sinensis* is 15.61 ± 1.06 where 1C DNA amount in terms of mega base pair (Mbp) is 3824 (Hanson *et al.*, 2001) and 1 pg (picogram) = 980 Mbp (Cavalier-Smith, 1985). Generally, chromosomes are small in size and tend to clump together due to “stickiness”. Tea is diploid ($2n = 30$; basic chromosome number, $x = 15$) and karyotype of chromosome ranges from 1.28 to $3.44 \mu\text{m}$ (Bezbaruah, 1971). The r value (ratio of long arm to short arm) for all the 15 pairs of chromosomes range from 1.0 to 1.91. This consistency in diploid chromosome number suggests a monophyletic origin of all *Camellia* species. However, few higher ploidy levels, such as triploids, e.g., Tocklai Vegetative (TV)-29, HS-10 A, United Planter Association of South India (UPASI)-3, UPASI-20 ($2n = 45$), tetraploids ($2n = 60$), pentaploids ($2n = 75$), and aneuploids ($2n \pm 1$ to 29) have also been identified among the natural tea populace (Singh, 1980).

Owing to extensive internal hybridization between different *Camellia* taxa, several intergrades, introgressants, and putative hybrids have been formed. These can be arranged in a cline based on morphological characters that extend from China types through intermediates to those of Assam types. Indeed, because of the extreme homogenization, the existence of the archetypes of tea is doubtful (Visser, 1969). To date, the numerous hybrids currently available are still referred to as China, Assam, or Cambod tea depending on their morphological proximity to the main taxa (Banerjee, 1992). Tea breeds well with wild relatives and thus tea taxonomists have always been interested in identifying such hybrids due to their suspected involvement in the genetic pool of tea. Two particularly interesting taxa are *Camellia irrawadiensis* and *Camellia taliensis* whose morphological distribution overlaps with

that of tea (Banerjee, 1992). It has also been postulated that some desirable traits, such as anthocyanin pigmentation or special quality characters of Darjeeling tea, might have been introduced to tea gene pool from wild species (Wood and Barua, 1958). Other *Camellia* species that are suspected to have contributed to the tea genetic pool by hybridization include *Camellia flava* (Pifard) Sealy, *Camellia petelotii* (Merrill) Sealy (Wight, 1962), and possibly *Camellia lutescens* Dyer (Sharma and Venkataramani, 1974). The role of *C. taliensis* is, however, not clear because the species itself is considered to be a hybrid between *C. sinensis* and *C. irrawadiensis* (Wood and Barua, 1958; Visser, 1969). Therefore, it is generally agreed that at least three taxa, i.e., *C. assamica*, *C. sinensis*, *C. assamica* subsp. *Lasiocalyx*, and to an extent *C. irrawadiensis*, have mainly contributed to the genetic pool of tea. The term “tea” should, therefore, cover progenies of these taxa and the hybrids thereof or between them.

1.6 Economic Importance and Health Benefits

The economic importance of the genus *Camellia* is primarily due to tea. Apart from being used as a beverage, leaves of tea are also used as vegetables like the “leppet tea” in Burma and “meing tea” in Thailand. While *Camellia oleracea* produces oil, used in the cosmetic industry, *Camellia sasanqua*, *Camellia Japonica*, and *Camellia reticulata* have great importance due to their ornamental values. Tea seeds yield about 17.3% of oil as compared to that of *C. sasanqua* (58%) and *C. japonica* (66%). The oil is of nondrying class and resembles the oil of *C. sasanqua* by its properties and characteristics. Although the oil is used as a lubricant, extraction of oil from tea seed is not economically viable (Wealth of India, 1950). Moreover, tea seed cakes also contain saponins. Although it has a poor value as a fertilizer and is unfit for animal feed on account of its low nitrogen, phosphorus, and potassium contents, yet at present it is being successfully utilized in the manufacture of a nematocide (Wealth of India, 1950).

Though tea is mainly consumed in the form of “fermented tea” or “black tea”, yet “nonfermented” or “green tea” and lesser known

“semifermented” or “oolong tea” are also available. These types vary in their method of manufacture, chemical constituent, appearance, and organoleptic taste. While black tea is widely used in India and other European countries, green tea is popular in China, Japan, and Taiwan. Oolong tea is mainly consumed in some parts of China as well as Taiwan. Worldwide 80% black tea, 18% green tea, and 2% oolong tea are being produced.

For black tea, the young tender leaves are completely fermented after withering. The fermentation results in oxidation and polymerization of polyphenols, changing the nature of the chemical constituents of tea leaves and forming theaflavin and thearubigin. These polyphenols are responsible for the briskness, strength, color, taste, aroma, and pungency associated with black tea. The infusion of black tea has a bright red or copper color, astringent taste and characteristic aroma. On the other hand, green tea is unfermented and is the least processed among the three types. The plucked leaves are harvested and steamed immediately to inactivate the enzymes to prevent oxidation and polymerization of primary polyphenols that result in retaining of green color in the finished product. Green tea infusion has a leafy taste and a smell of fresh vegetables, and low caffeine content. In oolong tea, the primary polyphenols are allowed to partly oxidize. Oolong tea is not common and is intermediate in characteristic between green and black tea. Immediately after plucking, the tea leaves are partially fermented for about half the time of black tea. It has the color of black tea and flavor of green tea.

Tea was used initially as medicine, later as beverage, and has a proven future potential of becoming an important industrial and pharmaceutical raw material. Scientific reports in the last two decades have validated many beneficial claims for tea. The majority of the beneficial effects have been attributed to the polyphenolic constituents. Several studies suggest that phenolics may be of importance in reducing the incidence of degenerative diseases, such as cancer and arteriosclerosis. The most relevant compounds in dietary regime are cinnamic acid derivatives and flavonoids. As natural polyphenols remain unchanged in green tea, it can be said that green tea is more beneficial than black tea. The strong antioxidant properties that sequester metal

ions and scavenge oxygen species as well as free radicals (Wiseman *et al.*, 1977) are responsible for beneficial effects of tea.

Tea catechins have been found to be better antioxidants than vitamin C, E, and carotene. The polyphenols block free radicals' damage to lipids (found in cell membranes and serum lipids), nucleic acids, and proteins (like those found as cellular enzymes and structural proteins). Damage to these cell components can lead to tumor formation.

Tea polyphenols and flavonoids have been reported to inhibit either enzymatic or nonenzymatic lipid peroxidation, an oxidative process implicated in several pathological conditions including atherosclerosis (Chen *et al.*, 2000). Besides, polyphenols have anticancer activity (Vasisht *et al.*, 2003), antidiabetic effect (Gomes *et al.*, 1995), antiarthritic activity (Tapiero *et al.*, 2002), antiplaque activity (Yu *et al.*, 1995), antiviral activity (Okubo and Juneja, 1997), anti-AIDS activity (Hashimoto *et al.*, 1996), anorectic effect (Kwanashie *et al.*, 2001), antimicrobial activity (Hamilton-Miller, 1995), and numerous other activities such as neuromuscular, antiangiogenic, antihepatotoxic, antiproliferative/apoptotic, and immunomodulatory effects (Sueoka *et al.*, 2001).

1.7 Traditional Breeding

The plant improvement program of tea can be classified into introduction, selection, and hybridization, which resulted in the development of more than 600 cultivated varieties with better yield, quality, and traits, such as resistance to drought, diseases, etc., by different tea research institutes and dedicated planters across the world (Mondal *et al.*, 2004).

1.7.1 Introduction

Barring China and India, most of the tea-growing countries initially undertook the massive introduction programs either to popularize the cultivation or to widen the germplasm base for developing improved cultivars befitting the need of that region, which are discussed below.

Tea propagule, such as seed, was primarily introduced from China to different countries including India, Japan, or Korea, etc. either by the

Buddhist pilgrimage or by colonial soldiers during the 8th century to be used as medicinal beverage.

Secondary introduction always happened after developing the improved varieties from the initial planting materials established through the primary introduction by the commercial tea growers with their personal efforts, and information regarding this is scant as stringent quarantine rules prevailed across the world for carrying the plant propagule. Interestingly, the early records indicate that around 60% world's acreage has received its initial planting material directly or indirectly from tea genetic resources of Tocklai Experimental Station of India. Initially, the commercial tea estate was established and later that was used as breeding stock for developing the new cultivar.

1.7.2 Selection

Selection is the most popular, age-old practice in tea breeding. Since commercial tea gardens were established earlier with seeds, a great variability exists among them. Many instances of elite plants have been identified among the existing bushes, multiplied vegetatively and released as clones. Majority of the tea clones have been developed through selection. TV-1 is a good example of a popular clone that was developed for north India. However, pedigrees of the clone remain unknown.

1.7.3 Hybridization

Hybridization in tea can be either natural or by hand pollination. In natural hybridization, based on known characters, such as previous performance of yield, quality or diseases resistance, two parents are planted side by side in an isolated place and allowed to bear fruits. Subsequently, the seeds (F_1) are harvested, raised, and planted. If average performances of these plants are found to be better than either parent, then seeds are released as hybrid seed or biconal seed. However, some of the outstanding performers among these progenies are marked and verified for multilocation trial and if still found suitable released as clones. These clones are geographically specific and most of the tea research institutes of the world have generated the clone for their own regions. Sometimes in the above process more than two parents are used,

known as polyclonal seeds. The idea is to introduce more variability among the F_1 seeds. Since it is difficult to know about the pedigree of the cultivar (as pollen may come from any male), the chance of reproducibility is low, and the process is thus least preferred presently.

Artificial or hand pollination or controlled crossing, despite being important approach, has met a limited success in tea breeding. The reasons identified could be the following: (i) low success rate; (ii) availability of tea flower for a short period (2–3 months); (iii) long time taken for seed maturation (12–18 months); and (iv) differences in flowering time of different clones. A few clones have been released in Kenya and Malawi recently using this technique.

1.8 Breeding Objectives

Tea breeding programs vary from country to country depending upon the local needs. The various objectives in different regions along with the probable genes are furnished in Table 1. However, by and large they are focused on improving quality and yield.

However, in general, the breeding work at black tea producing countries such as India, Kenya, and Sri Lanka is biased toward the development of clones with high yield and better quality whereas the green tea producing countries near equator such as Japan, China, etc. are focused on the development of cold-resistant and frost-resistant clones.

1.9 Rationale of Development of Transgenic Tea

Production of desired plant types of human choice through conventional breeding is an age-old practice in agriculture. Although, conventional tea breeding is well established and contributed much for tea improvement over the past several decades, the process is slow due to some bottlenecks. Specifically in tea, they are as follows: (1) perennial nature, (2) long gestation period, (3) high inbreeding depression, (4) self-incompatibility, (5) unavailability of distinct mutants to withstand different biotic and abiotic stresses, (6) lack of distinct selection criteria, (7) low success rate of hand pollination, (8) short flowering time, i.e.,

Table 1 Breeding objectives in tea

Objectives	Importance	Region	Transgenic solution
Improving quality	Directly linked to the profitability	Black tea producing countries such as India, East Africa, Sri Lanka, Bangladesh, and Indonesia	Chalcone synthetase, phenyl ammonia lyase, etc.
Increasing yield	Horizontal increase of production by extension planting is limited worldwide	Worldwide	<i>rolb</i> gene
Drought tolerance	Reduces productivity and occurs in all tea-growing regions in the world	Worldwide where tea grows as a rain-fed crop	Absciscic acid induced (<i>abi3</i>) gene
Reduce winter dormancy	No leaf production during winter months and occurs in northeast India, Japan, China, etc.	Tea plantation in near equator	Superoxide dismutase (Cu/Fe/Zn <i>sod</i>) gene
Hail resistance	Causes economic loss as young leaves during rainy season are mostly affected; generally occurs in the hilly region	Hilly region of the tea producing countries	Genes need to be identified
Water-logging tolerance	Reduce productivity during rainy season; generally occurs in northeastern India	Northeast India	Ascorbate peroxidase (<i>apx3</i>) gene
Cold hardiness	Reduced productivity during winter due to snow; generally occurs in Japan and Russia	Mainly Japan, Russia, and China	Glycerol 3-phosphate acyltransferase (<i>gpat</i>) gene
Resistance to diseases such as blister blight, stem canker, etc.	Blister blight causes severe damage as only young leaves are infected; generally occurs in Japan, Sri Lanka, south India, and Darjeeling hills of northeast India	Mainly India, Sri Lanka, Indonesia, and Japan	Chitinase, ribosome inactivating proteins, etc.
Resistance to pests such as red spider mite, tea mosquito bug, leaf sucking pest, etc.	Most important biotic stresses as all cause severe damage to the leaves; generally occur in all the tea-growing regions in the world	Worldwide	<i>Bt</i> , plant lectins, and proteinase inhibitor gene
Suitability to type of manufacturing	For matching the customer's demand as well as better recovery percentage in made tea	Black tea producing countries such as India, East Africa, Sri Lanka, Bangladesh, and Indonesia	Genes need to be identified
Low input responsive clone	Required for organic tea farming	Organic tea	Genes need to be identified

2–3 months, (9) long duration for seed maturation, i.e., 12–18 months, and (10) clonal difference of flowering time and fruit-bearing capability in some clones. Thus transgenic technology is a better alternative as it has several advantages; important among them are as follows: (1) any origin of gene can be transferred; (2) greater speed; (3) expression of transgenic being free from epistatic interaction. Due to the nonavailability of new land for expansion of cultivation along with the objectives of reducing the cost of cultivation, tea breeders need to develop the improved tea cultivars as per the requirement of the industry. Therefore, gene transfer through biotechnological

means appears to be not only a time effective but also an advantageous better alternative.

2. DEVELOPMENT OF TRANSGENIC TEA

2.1 *In Vitro* Culture

Like any other woody plants, *in vitro* culture of tea focuses mainly on micropropagation and somatic embryogenesis both of which are utilized to develop transgenic plants. However, central to any successful transgenic technology is an efficient *in vitro* regeneration protocol. While regeneration

method is essential for the introduction of foreign genes into plant tissues, micropropagation is important for the transfer of a large number of genetically modified (GM) plants to the field within a short span of time.

The micropropagation works in tea have been reviewed from time to time (Vieitez *et al.*, 1992; Dood, 1994; Das, 2001; Mondal, 2002; Mondal *et al.*, 2004). It is clearly evident that the development of micropropagation of tea passed through three different phases. Till 1980s, the emphasis was to standardize the parameters of *in vitro* protocol, such as suitable explant, overcoming the microbial contamination, and optimization of media composition along with growth regulation for better proliferation. It is now widely adopted that nodal segments (0.5–1.0 cm) cultured on a Murashige and Skoog (MS) medium with 6-benzylaminopurine (BAP) ($1\text{--}6\text{ mg l}^{-1}$) is the best for multiplication of shoots along with either a high-dose (500 mg l^{-1}) pulse treatment of auxin, such as indole-3-butyric acid (IBA), or a low dose ($1\text{--}2\text{ mg l}^{-1}$) for long duration is suitable for *in vitro* rooting. Later, till 1990s, efforts were made toward the hardening of microshoots to achieve a higher percentage of survival. Accordingly, several nonconventional approaches, such as CO₂-enriched hardening chamber, biological hardening, and micrografting were developed. Presently, attention is paid to the evaluation of field performance of the micropropagated plants.

One of the prerequisites for genetic transformation of tea is to develop an efficient regeneration system from a single cell to complete plant. Till today, somatic embryogenesis is considered to be the most efficient regeneration system for tea. Several reviews have been documented in the recent past (Akula and Akula, 1999; Mondal *et al.*, 2004) that indicate that though Wu *et al.* (1981) initiated the work of somatic embryogenesis in tea, the technology has been applied for several purposes today, such as clonal propagation (Mondal *et al.*, 2001a), genetic transformation (Mondal *et al.*, 2001b), artificial seed production (Mondal *et al.*, 2000), some interspecific crosses of *Camellia* (Nadamitsu *et al.*, 1986), and androgenic or haploid plant production of tea (Chen and Liao, 1982). Somatic embryogenesis of tea depends upon several factors, such as explants' type (Akula and Akula, 1999), time of culture (Mondal *et al.*, 2000), and genotypes (Kato, 1996).

Type, concentration and time of application of different plant growth regulators (PGRs) have also been extensively worked out. In general, a high cytokinin to low auxin ratio or low cytokinin alone was found to be necessary for the induction of somatic embryos in tea; even reduction or omission of cytokinin in subsequent subculturing is also known. Generally, 6-benzyl adenine ($0\text{--}10\text{ mg l}^{-1}$) has been widely used for tea and related species (Zhuang and Liang, 1985) followed by kinetin ($0.05\text{--}10\text{ mg l}^{-1}$) (Wachira and Ogado, 1995). Among the different auxins, IBA ($0\text{--}2\text{ mg l}^{-1}$) was used mostly for somatic embryo induction in tea. However, different concentrations of α -naphthalene acetic acid (NAA) (Balasubramanian *et al.*, 2000), 2,4-dichlorophenoxyacetic acid, indole-3-acetic acid (Sood *et al.*, 1993) and α -naphthoxyacetic acid, tetraphenylboron, and phenylboronic acid (Ponsamuel *et al.*, 1996) were also used.

Apart from growth regulators, some other factors, such as nitrate salts of potassium and ammonium, together with sulfate salts of aluminum, potassium, magnesium, and ammonium, sucrose concentration as well as maltose and transcinamic acid (Mondal *et al.*, 2002), brassin, a synthetic analog of a naturally occurring brassinoid (Ponsamuel *et al.*, 1996), also have a positive role for tea embryogenesis.

Hitherto, emphasis has been given to manipulate the nutrient composition, growth regulators in the culture medium, physical conditions of incubation, and other stress treatments to induce somatic embryos. However, induction of *in vivo* embryogenesis of tea could be achieved without using the conventional tissue culture media (Mondal *et al.*, 2001c). Though reason for this observation is not clear presently, yet seeds of *Camellia* appear to have a considerable inherent capacity for embryogenesis. Thus, at the right physiological stage, with appropriate levels of internal hormone and appropriate moisture profile of the substrate under sterile conditions, the tea seeds are able to produce embryos without any exogenous nutrient.

2.1.1 Hardening

Information on hardening of tea somatic embryo-derived plants is scant in the literature. Although Wu *et al.* (1981) were the first to transfer the

plantlets to soil, the composition of soil mixture and other conditions used by them were not mentioned clearly. Later, Kato (1996) grew healthy tea somatic seedlings under natural conditions by transferring them into a mixture of vermiculite and soil (1:1) and they were covered under the plastic. On the other hand, Jha *et al.* (1992) hardened tea plantlets for 8 weeks in quarter-strength MS salts before transplanting to pots containing a mixture of peat and soil (1:1) and achieved an acclimatization rate of 70%. Wachira and Ogado (1995) reported that multiple shoots differentiated from the germinated embryos were successfully rooted in mixture of sand:peat (3:1) in small pots. In order to improve rooting, Ponsamuel *et al.* (1996) treated the plantlets with 1 mM indole-3-acetonitrile, 1 mM brassin, and 10 mM phloroglucinol in a liquid MS medium for 15 days, and after profuse root proliferation, the plantlets were acclimatized in pots containing vermiculite. Eventually, the plants were transplanted in the greenhouse.

Akula and Akula (1999) transferred the small plantlets with a strong tap root and four to six leaves into small pots filled with a presterilized potting mixture (sand:peat:vermiculite—1:2:1) and kept in a greenhouse with misting facility, at 80–95% humidity under low light. The new leaves were observed within 5–6 weeks when they were taken into bigger pots. Following this procedure, they achieved a 90–95% survival rate and more than 200 plantlets were transferred to the field in Indonesia. Tea plantlets with young leaves and stout roots, with a height of 4–5 cm, were taken from culture room to Hikko-trays containing presterilized sand and cow dung (1:1). These Hikko-trays were then kept in a polytunnel with intermittent watering for 60 days inside an indigenously developed polyhouse (90% survival rate). Later, they were transferred to polythene sleeves filled with black virgin soil and kept for further 1 year in the same polyhouse (Mondal *et al.*, 2001a). Following these techniques, they could produce 3000 somatic seedlings at the Research and Development Department of Tata Tea Ltd, India, which have been transferred to the field.

Perhaps the most critical phase of *in vitro* culture is the establishment of plantlets to the greenhouse. In tea, a commendable progress has been made that deserves a special merit to elaborate.

Conventionally, tea microshoots are hardened for 6 months on soil mixture containing various additives such as cow dung, soil rite, etc. and then kept inside the indigenously developed polytunnel with various shapes and sizes. Generally, the standard procedure is to transfer the rooted plantlets of tea to potting mixtures containing peat and soil (1:1) under high humidity created by using misting or fogging units (Banerjee and Agarwal, 1990; Agarwal *et al.*, 1992), but use of vermiculite:soil (1:1) has also worked very well (Kato, 1985). Detailed studies with various parameters, such as time of harvesting of microshoots, shoot size, soil pH, PGRs, CO₂ enrichment, and light condition, were carried out by Sharma *et al.* (1999). Among the different parameters, soil pH coupled with CO₂ enrichment is the most critical factor for hardening to achieve a high percentage of survival rate.

Importantly, to overcome the mortality due to microbial contamination at the hardening stage, biological hardening has been developed by Pandey *et al.* (2000) who found that when microbial inoculants of two bacteria, *Bacillus subtilis* and *Pseudomonas corrugate*, are used during hardening of micropropagated shoots, the survival rate increases significantly in all the three seasons: rainy, winter, and summer.

Micrografting is a new alternative strategy for hardening the micropropagated shoots of woody plants. In this strategy, *in vitro* raised scions are directly transplanted either on *in vitro* raised rootstocks under sterile conditions or *in vivo* raised stocks. In tea, this technique has been standardized (Prakash *et al.*, 1999; Mondal *et al.*, 2005), which indicated not only a survival rate more than 95% but also shortening of the hardening time by 1 year due to a faster growth rate of micrografted shoots. This has immense potential in tea where breeding work suffers due to a long gestation period.

2.1.2 Field performance

The ultimate success of any *in vitro* protocol depends upon the performance of the plants in the fields as compared to their vegetative counterparts. The Research and Development Department of Tata Tea Ltd, India, is the pioneer, where more than 45 000 plants of eight different cultivars

of tea were transferred to the field, and leaves from those plants are being harvested regularly to manufacture black tea for last several years.

From a study on 1.7-, 4-, and 8-year-old field-grown micropropagated and vegetatively propagated tea plants in the laboratory of the above department and elsewhere in India, it was observed that overall yield and quality were comparable. Although the different physiological parameters such as photosynthetic rate, chlorophyll content, etc. remained the same, two different morphological variations were noticed. The number of lateral shoots produced after “centering” were significantly more in micropropagated plants as compared to the vegetatively propagated plants. This is perhaps due to the effects of the various growth regulators that the tissue culture raised plants experienced under *in vitro* conditions. The root volumes of tissue culture plants were also higher than those of the vegetatively propagated plants. The reason might be that the micropropagated shoots were treated with IBA to induce rooting, which could be responsible for better root development in the field. Therefore, it can be concluded that the micropropagation protocol should be used only

when there is a need to produce high number of propagules from a limited source.

2.2 Genetic Transformation

The development of transgenics in tea is furnished in Table 2 and explained below.

2.2.1 *Agrobacterium tumefaciens*

The first protocol for production of transgenic tea, *C. sinensis* (L.) O. Kuntze cv. Kangra jat, was developed via *Agrobacterium*-mediated genetic transformation (Figure 1; Mondal *et al.*, 2001b). Two disarmed *A. tumefaciens* strains, EHA 105 and LBA 4404, both carrying the binary plasmid p35SGUS-INT with the *nptII* (neomycin phosphotransferase II) gene and *gus* (β -glucuronidase) intron were evaluated as vector systems. Several parameters were evaluated to maximize the transformation efficiency. While preculture, wounding, and acetosyringone treatment in different concentrations were inhibitory, the bacterial growth phase (optical density: OD₆₀₀ = 0.6), cell

Table 2 A chronological summary of transgenic tea research

Serial number	Techniques used	Remarks	References
1	<i>Agrobacterium tumefaciens</i>	Antibiotic selection for <i>Camellia</i> species was reported	Tosca <i>et al.</i> , 1996

Surface disinfection of mature sinker seeds

Germination on half MS + 30 g l⁻¹ sucrose + 0.7%

2 weeks

Induction of somatic embryos from cotyledon slices on half MS + 20 g l⁻¹ sucrose + 2.5 g l⁻¹ NAA + 0.2 g l⁻¹ BAP

6–8 weeks

Multiplication of primary embryos on embryo multiplication medium (EMM) MS + 2 g l⁻¹ BA, 0.2 g l⁻¹ IBA, 1.0 g l⁻¹ L-glutamine

6 weeks

Infection of globular embryos with *Agrobacterium* suspension (OD₆₀₀ = 0.6 × 10⁹ cells/ml)

20 min

Co-cultivation in EMM medium (pH 5.6) in darkness

5 days

Washing two times with sterile water and two times with liquid EMM containing 400 mg l⁻¹ sporidex and blot drying

Transfer of embryos to EMM + sporidex (250 mg l⁻¹) + carbenicillin (250 mg l⁻¹)

2 weeks

Selection on above medium + kanamycin (50 mg l⁻¹)

8–12 weeks

Transfer to MS + 40 g l⁻¹ maltose + 3.0 g l⁻¹ trans-cinamic acid + kanamycin (75 mg l⁻¹)

4 weeks

Transfer to MS + 1.5 mg l⁻¹ GA3 + kanamycin (75 mg l⁻¹)

8 weeks

Multiplication of transgenic shoots on MS + 1 mg l⁻¹ TDZ + 2 mg l⁻¹ NAA

8 weeks

Micrografting on seedling rootstocks and growth in greenhouse

Figure 1 Protocol for *Agrobacterium*-mediated genetic transformation

density (10⁹ ml⁻¹), co-cultivation period (5 days), and pH of the co-cultivation medium (5.6) had positive effects on transformation. Following co-cultivation, globular somatic embryos were placed on a multiplication medium and stressed with kanamycin (50 mg l⁻¹). Further selection occurred in the maturation and germination medium at an elevated kanamycin level (75 mg l⁻¹). An average of 40% transient expression was registered based on the GUS histological assay (Figure 2). Then the kanamycin-resistant, GUS-positive embryos were germinated and the resulting microshoots were

multiplied *in vitro* on a MS medium fortified with 5 µM thidiazuron and 10 µM NAA. Later, they were micrografted onto seed-grown rootstocks (Mondal *et al.*, 2005) of cv. Kangra jat and eventually hardened in a walk-in polyhouse. Integration of the transgenes into the tea nuclear genome was confirmed by polymerase chain reaction (PCR) analysis using *nptII*- and *gus*-specific primers and by southern hybridization using an *nptII*-specific probe.

However, use of phenolic inducer, acetosyringone, did not enhance the efficiency of

Figure 2 *Agrobacterium*-mediated genetic transformation of tea somatic embryos: (a) blue spot indicating gus activity after 48 h of infection; (b) a gus-positive secondary somatic embryo of 4 months old; (c) a hand section of leaf tissue of transformed shoot of 12 months old; (d) kanamycin selection; (e) PCR amplification of a 693 bp fragment of *nptII* gene (lane M: DNA double digested with *Eco*R1 and *Hind*III; lane C: DNA from untransformed tea plant (control); lanes 1–5: DNA from independently transformed plants; (f) the greenhouse-grown transgenic tea plants (Mondal *et al.*, 2002)

transformation (Mondal *et al.*, 2005). In several other experiments on woody plants, acetosyringone did not help in increasing transformation efficiency (Confalonieri *et al.*, 1997). The inability of acetosyringone to improve the transformation efficiency could be due to the inherent prevalence of high amounts of phenolics in tea. Contrary to this, Matsumoto and Fukui (1999) found that acetosyringone has a positive role in tea transformation as this plant is considered to be one of the recalcitrant plants for *Agrobacterium* infection. Naturally occurring crown galls are hardly observed on tea plant and this bacterium is not cited as an economically important pathogen in Japan. Therefore, they concluded that the low efficiency of the *Agrobacterium* infection was overcome by acetosyringone. Resistant calli emerged only on the explants treated with a higher concentration of acetosyringone. Thus, they concluded that application of 100 μ M acetosyringone to a co-culture medium was effective for tea transformation.

Another important factor that affects transformation efficiency is the selection of transgenic tissue on an antibiotic medium. In order to select transformed explants, selective agents are added into the medium to produce selective pressure. In general for tea, among the different antibiotics, hygromycin was more effectively used at a low concentration (20 mg l^{-1}) for somatic embryos followed by kanamycin with a range from 50 to 200 mg l^{-1} . In a wild species of tea, Tosca *et al.* (1996) found that 75 mg l^{-1} kanamycin was lethal to the tissues. Similarly, Mondal *et al.* (2001b) reported that 50 mg l^{-1} kanamycin followed by an elevation of kanamycin to 75 mg l^{-1} were the levels to be used for the effective selection of tea somatic embryos. On the other hand, Matsumoto and Fukui (1998, 1999) found that 200 mg l^{-1} kanamycin was effective for tea when leaves were used as explants.

Another prerequisite for genetic transformation is the molecular characterization of putative transformants. While Matsumoto and Fukui

(1998, 1999) have reported stable transformations in callus on the basis of PCR analysis and southern hybridization, it were Mondal *et al.* (2001b) who reported on stable transformed transgenic tea plants after molecular characterization. They found that 5 out of 12 independent kanamycin-resistant and GUS-positive lines yielded positive PCR amplification. This indicated the presence of the marker kanamycin (*nptII*) linked to the *gus* gene as a single “transfer-DNA (T-DNA) strand” in the genomic DNA of the transformed plant. The failure of the rest of the lines in yielding PCR-amplification products may be attributed to the presence of “false positives” during the antibiotics selection. Further, when the leaves of these five independent transgenic plants were subjected to Southern blot analysis, *Pst*I digests of genomic DNA from each of four putative transgenic lines generated an internal transgene fragment of 1.6 kb that hybridized to the *nptII* probe. Additional shorter fragments produced in some transgenic lines further indicated a deletion of a part of the T-DNA containing *nptII*. The deletion might perhaps occur during transformation or regeneration. Different banding patterns observed in the southern hybridization could be due to multiple insertion, rearrangement, and/or deletions of the integrated transgenes in the regenerated plants as is common to *A. tumefaciens*-mediated transformation (Mercuri *et al.*, 2000). Although 80–90% survival of transgenic plants was achieved under greenhouse conditions, the stability of the transgene remains to be elucidated as tea plants take years to flower and set seeds.

The host range specificity between the bacterium and five different tea cultivars as well as an unrelated plant, *Artemisia parviflora*, having extreme surface characteristics was evaluated (Kumar *et al.*, 2004). The degree of *Agrobacterium* infection in the five cultivars of tea was affected by leaf wetness, micromorphology, and surface chemistry. Wettable leaf surfaces of TV-1, UPASI-9, and Kangra jat showed a higher rate (75%) of infection. This indicated that the leaves with a glabrous surface having lower Ø (large surface area covered by water droplet) and higher phenol and wax content were suitable for *Agrobacterium* infection. Caffeine fraction of tea promoted *Agrobacterium* infection even in leaves containing less wax (UPASI-10), whereas caffeine-free wax inhibited both *Agrobacterium*

growth and infection. Thus, this study suggests the importance of leaf surface features in influencing the *Agrobacterium* infection in tea leaf explants.

Considering the fact that lepidopteran and coleopteran insects account for 31.5% and 18.8% crop loss, respectively, in China, Luo and Liang (2000) pioneered for constructing a vector containing *Bt* (*Bacillus thuringiensis*) gene and transformed tea. The vector pGA471 containing *Bt* gene was digested with *Hind*III and *Bgl*II and inserted into the vector pCambia2301. The constructed plasmid with *Bt* gene (*cryIac*), *GUS* intron gene, and *NPTII* was transformed into *Escherichia coli* and introduced into *Agrobacterium* strains LBA 4404, EHA 105, and pRi15834 through a triparental cross. They detected the transient expression of *GUS* gene in calli and leaves of putative transgenic tea plants. However, no transgenic plants were recovered.

Three genes including *rolb*, *Bt*, and *Chitinase* have been transferred to tea cv. TTL-1 at the Research and Development Department, Tata Tea Ltd, Kerala for developing a tea plant with better yield, pest resistance, and resistance to blister bight disease. Preliminary study indicates that there is no difference in quality of Centro de Tecnologia Canavieira (CTC)-made tea in the transgenic plant but *rolb* produces more root and shoot biomass in 2-year-old young transgenic plants (data not shown).

Later, Lopez *et al.* (2004) also produced transgenic tea. Cotyledon-derived embryogenic callus cultures were co-cultivated with *A. tumefaciens* harboring a binary vector carrying the hygromycin phosphotransferase (*hptII*), glucuronidase (*uidA*), and green fluorescent protein (*GFP*) genes. Following co-cultivation, embryogenic calli were cultured in a medium containing 500 mg l⁻¹ carbenicillin for a week and then transferred on an antibiotic selection medium containing 75 mg l⁻¹ hygromycin for 8–10 weeks. Hygromycin-resistant somatic embryos were selected. The highest production efficiency of hygromycin-resistant calli occurred with co-cultivation for 6–7 days in the presence of 400 µM acetosyringone (AS). Hygromycin-resistant somatic embryos developed into complete plantlets in a regeneration medium containing half-strength MS (1962) salts with 1 mg l⁻¹ BAP and 9 mg l⁻¹ gibberellic acid A3. Transformants were subjected to GFP expression analysis, β-glucuronidase (GUS) histochemical

Figure 3 (a) Stable GFP expression following *Agrobacterium*-mediated genetic transformation of embryogenic calli (bar: 3 mm); (b) nontransformed control callus without GFP expression (bar: 3 mm); (c) GFP expression in the cross-section of the transformed callus [Reproduced from Lopez *et al.* (2004) with permission]

assay, PCR analysis, and southern hybridization to confirm gene integration. The GFP is a stable, cell-autonomous fluorescent protein derived from jellyfish (*Aequorea victoria*). It has been extensively used as a nondestructive reporter gene for plant transformation (Chiu *et al.*, 1996). After 30 days of co-cultivation, GFP expression was evident in calli. Nontransformed tissue from original explants did not express green fluorescence, and explant growth was suppressed (Figures 3a–c). Leaves of transformed plantlets also expressed GFP, and the green fluorescence was easily detectable with blue light illumination of calli.

Production of transgenic tea tissue was also reported by Jayaraman and Nithya (2005). Embryogenic tissues of tea were co-cultivated with *A. tumefaciens* strain LBA4404. The plasmid pBi121, which contains the *nptII* gene providing kanamycin resistance as a selectable marker and the β -glucuronidase (*uidA*) reporter gene, was used as binary vector. The highest transformation frequency (12 transformants per gram fresh weight of treated embryogenic tissue) was obtained with 5-day-old tissues grown in a liquid medium and co-cultivated with *Agrobacterium* for 2 days in the same medium but containing 50 μ M AS. There was improvement in the recovery of kanamycin-resistant tissues when tissues were first grown for 10 days on a medium containing 350 mg l⁻¹ Timentin to prevent bacterial overgrowth, before application of the selection pressure. Resistant tissues obtained after 6 weeks on the kanamycin selection medium showed a stable *uidA* expression. PCR analysis demonstrated

the presence of the transgenes, while southern hybridization confirmed their integration into the genome. Following this protocol, they could produce transgenic plants within 4 months after co-culture. As reported for other species (Bergmann and Stomp, 1992; Sangwan *et al.*, 1992), the physiological status of the tissue was considered to be an important factor for successful transformation of tea. They found that rapidly dividing embryogenic suspension culture, obtained 5 days after a 7 days subculture, provides suitable material to achieve a high frequency of transformation. Additionally, co-cultivation in a liquid medium and addition of 50 μ M AS were essential for successful transformation. AS is a low-molecular-weight phenolic compound naturally released by wounded plant cells and acts as an inducer of the virulence genes. For tea, the use of AS probably increases tDNA transfer, as reported in a wide range of plant species (Godwin *et al.*, 1992). It was also shown that Timentin, when used at a high concentration (350 mg l⁻¹), provided better protection against bacterial overgrowth than did cefotaxime and carbenicillin. By using Timentin instead of cefotaxime or carbenicillin, the costs associated with antibiotic use were reduced. Finally, a two-step procedure for screening transformants such as first selection of transformed tissues and a second selection during the germination of putatively transformed embryos on a kanamycin-containing medium (25 and 50 mg l⁻¹, respectively) improved the rapidity and efficiency of the transformation procedure, allowing recovery of transgenic plants within 3–4 months after co-culture.

2.2.2 *Agrobacterium rhizogenes*

Several groups have also transformed the tea plant with *A. rhizogenes*. Zehra *et al.* (1996) infected *in vitro* tea leaves with *A. rhizogenes* A₄. A cell density of 10^8 ml^{-1} for 2 min infection followed by blotting on sterile filter papers and co-cultivation in dark for 2 days induced hairy roots after 35 days. The isolated hairy roots grew healthy in the liquid medium. Mannopine from these roots were analyzed through paper electrophoresis, which confirmed stable integration of the gene. Later, Konwar *et al.* (1998) also transformed 4–6-month-old *in vitro* grown tea shoots by infecting at the basal portion followed by co-cultivation in a liquid basal MS medium supplemented with IBA (5 mg l^{-1}) and rifampicin (100 mg l^{-1}). Root initiation from the basal portion of 66% explants after 32–45 days culture enabled convenient hardening of the shoots in pots or nursery beds.

2.2.3 Biolistic-mediated transformation

Although no transgenic tea plants have produced via particle gun, a preliminary study on transient expression was reported by Akula and Akula (1999). Somatic embryos were bombarded with DNA (p2k7) coated gold particles ($1.5\text{--}3 \mu\text{m}$ diameter). The transformation vector p2k7, which was used in their study, was originally derived from binary vector pBI 221 with *NPTII* gene and *gus* gene. Both genes were driven individually by the cauliflower mosaic virus 35S promoter. The gold particles were coated with DNA ($1 \mu\text{g} \mu\text{l}^{-1}$) by precipitation with CaCl_2 (1 M) and spermidine (0.1 M). Optimization of various factors such as the distance between the site of delivery of the microprojectile and the target tissue, helium pressure, and the state of target tissue to obtain transient expression were evaluated on the basis of β -glucuronidase (GUS) assay after 30–40 h of bombardment. Following bombardment, the highest transient expression levels (up to 1085 blue spots/shoot) were obtained in the somatic embryos using a helium pressure of 550 kPa with target tissue at a distance of 9.5 cm from the site of delivery of DNA. Mannitol pretreatment did not influence the transient expression as

both control and treated cultures gave the same level of expression. However, further details of regeneration of transgenic somatic embryo were not mentioned.

3. FUTURE ROAD MAP

Despite the fact the transgenic technology has tremendous scope for tea, no transgenic plants have been cultivated commercially so far. Among the many reasons, a few could be as follows: (1) tea plant is not easily amenable for *Agrobacterium* infection; (2) nonavailability of generic protocol, which can be applied for a wide range of varieties of tea plant; (3) being woody perennial, production of transgenic tea is time consuming and hence private funding is less. However, it is evident now that among the different techniques *A. tumefaciens*-mediated transformation has been attempted with different groups but transgenic tea is yet to be commercialized. On the other hand, though *A. rhizogenes* transformation in tea has been demonstrated, the technique has not been exploited commercially to produce the secondary metabolites so far, which will be immensely useful for a crop like tea. Contrary to the above techniques, work on particle bombardment is at very initial stages. It is noteworthy to mention here that perhaps transgenic tea has a unique advantage as, during processing, green tea leaves are exposed to a temperature of 120°C at the drying step during which toxins will be destroyed, which is critical for GM foods globally for some agricultural crops. A detail study through international collaboration by a common consortium will be the right approach for production of transgenic tea in the long term.

ACKNOWLEDGMENTS

The author is thankful to P.S. Ahuja, Director, IHBT, Palampur, India, and the management staffs of R&D Department of Tata Tea Ltd, Kerala, India, for their technical help and support to carry out some portions of the study.

1. INTRODUCTION

Natural rubber, cis-1,4-polyisoprene, produced in the milky cytoplasm (latex) of specialized cells, called laticifers, of certain plants, is one of the most important biological macromolecule, used as industrial raw material for the manufacture of a variety of products. Natural rubber has been found in the latex of over 2000 plant species belonging to 311 genera of 79 families. However, *Hevea brasiliensis* (Para rubber tree) remains as the only cultivated species as a commercial source of natural rubber because of its abundance in the latex, high quality, and convenience of harvesting. Nature has not provided any other industrial raw material of plant origin as flexible as natural rubber. Rubber has a number of applications and there is hardly any segment of life that does not make use of rubber-based material. All along this chapter, *H. brasiliensis* will be mentioned as rubber or rubber tree, unless otherwise a specific mention is required.

1.1 History, Origin, and Distribution

H. brasiliensis is a native of Amazon River basin of South America. Rubber is one of the recently domesticated crops in the world. The successful transfer of *H. brasiliensis* to Asia and the subsequent establishment of commercial

rubber plantations were in response to the growing demand for this raw material. *H. brasiliensis* was introduced to Tropical Asia in 1876 through Kew Gardens from the seeds brought from the Rio Tapajós region of the upper Amazon region of Brazil by Sir Henry Wickam (Dijkman, 1951). Kew Gardens, UK, played a special role in the domestication of wild plants. It was in the Kew Gardens where the planting materials were assembled from the native land, propagated, and then distributed to other botanical gardens around the world (Baulkwil, 1989). *H. brasiliensis* is now commercially cultivated in the tropical regions of Asia, Africa, and South America in countries like Indonesia, Thailand, Malaysia, India, China, Sri Lanka, Philippines, Vietnam, Nigeria, Cameroon, Ivory Coast, Liberia, Brazil, Mexico, etc. However, the major share comes from Tropical Asia.

1.2 Botanical Descriptions

1.2.1 Taxonomy

H. brasiliensis belongs to the family Euphorbiaceae. Ten species of *Hevea* have been identified in the genus, namely, *H. benthamiana*, *H. brasiliensis*, *H. camargoana*, *H. camporum*, *H. guianensis*, *H. microphylla*, *H. nitida*, *H. pauciflora*, *H. rigidifolia*, and *H. spruceana* (Schultz, 1990).

1.2.2 Botany

Rubber tree (*H. brasiliensis*) is a sturdy, quick-growing tree, which attains a height of 25–30 m. The tree has a straight trunk with light gray bark. Branches are usually developed to form an open leafy crown. The bark of the trunk is the part from where rubber is exploited (Figure 1). The young plants show a characteristic growth pattern of alternating periods of rapid elongation and consolidation. The tree is deciduous with annual leaf fall. Refoliation and flowering follow wintering. The leaves are arranged in groups or storeys. From each storey, a cluster of spirally arranged trifoliate glabrous leaves is produced. The petioles are long, usually about 15 cm, with extra floral nectaries present in the region of insertion of the leaflets (Premakumari and Saraswathyamma, 2000).

Rubber tree is a monoecious tree with diclinous flowers arranged in a pyramid-shaped panicle. The flowers are short stalked and fragrant. The flower has one whorl of bell-shaped yellow-colored perianth with five lobes. Male flowers are smaller in size but more in number than the female flowers. In the male flower, there are 10 sessile anthers arranged on a slender staminal

column in two whorls of five each. Each anther contains two pollen sacs that split longitudinally on dehiscence. Pollen grains are tricolpate, smooth, and sticky. Female flowers are seen at the tip of the panicle and its branchlets. When fully developed, they are recognizable by their relatively bigger size and the green torus basal disc. The gynoecium is tricarpellary and syncarpous with an ovule in each locule. The stigma is short styled and three lobed. Pollination is mediated by insects. Sticky pollen and stigmatic surfaces indicate the typical entomophilous nature of the flower. After fertilization the ovary will develop into a three-lobed dehiscent capsule, regma, with three large mottled seeds. Fruits ripen 5–6 months after fertilization (Kavitha and Saraswathyamma, 2005).

1.2.3 Habitat

Rubber tree could be predominantly grown in the tropics where an equatorial monsoon climate prevails. The optimum climatic conditions for the successful growth of rubber are as follows: (1) rainfall of 2000 mm or more, evenly distributed without any marked dry season, and with 125 to 150 rainy days per annum; (2) maximum temperature of about 29–34 °C; (3) high atmospheric humidity in the order of 80% with moderate wind; and (4) bright sunshine amounting to about 2000 h per annum at the rate of 6 h per day throughout all the months (Watson, 1989; Rao and Vijayakumar, 1992).

1.2.4 Cytology

The chromosome counts made by various investigators showed variations and reported as $2n = 16, 34$, and 36 . However, detailed cytological investigations have confirmed the chromosome complement of rubber tree in the somatic cells as $2n = 2x = 36$ (Ramaer, 1935; Saraswathyamma *et al.*, 1984). The chromosomes are small and vary in length and the total chromosome length of the species is 89.7 μm . Meiotic division is regular and pollen fertility is over 80%. Critical analysis of karyomorphology revealed significant differences between clones with reference to centromeric position and total chromosome

Figure 1 A rubber plantation (RRII 105 clone) at RRII with an enlarged view of the tapping region at the inset (arrow indicates latex flow into a cup from rubber tree after tapping)

length (Saraswathyamma, 1990). There are no chromosomal or genetic barriers between the 10 *Hevea* species. Triploid plants with $2n = 3x = 54$ (Nazeer and Saraswathyamma, 1987) and induced tetraploids with $2n = 4x = 72$ by the application of colchicine (Saraswathyamma, 1990) were also reported. Wide range of meiotic abnormalities was noticed in the triploids and tetraploids (Saraswathyamma, 1997). The cytophotometric determination of DNA content of various cytotypes revealed 44.2 pg (picogram) in the diploids, 62.4 pg in the triploid, and 89.37 pg in the tetraploids (Saraswathyamma, 1990).

1.2.5 Harvesting and processing

In rubber tree, natural rubber is synthesized in highly specialized cells called latex vessels, present in all parts of the tree except the heartwood. These latex vessels originate from the cells produced by the cambium and they are articulated and anastomosing (Hebant and de Fay, 1980). The milky cytoplasmic content (latex) is collected by the controlled wounding of the bark, called tapping. The rubber is separated from latex upon coagulation and further processing.

1.3 Economic Importance

The global area under rubber cultivation is about 9.6 million hectares producing 9.2 million tons annually valuing about US\$18 billion as raw material alone (IRSG, 2007). The major rubber producing countries are Thailand, Indonesia, India, Malaysia, China, Vietnam, etc. Chemically, natural rubber is *cis*-1,4-polyisoprene, having molecular weight of 200 000 to 8 000 000 and with viscoelastic properties. The flexibility of natural rubber to undergo vulcanization with sulfur under high temperatures is an important attribute. The higher strength, low heat build up, and better resistance to wear and flex cracking made natural rubber a suitable raw material for the manufacture of automobile tires. A major quantity of natural rubber produced is consumed by the automobile tire industry. Natural rubber is a good insulator and can be easily manipulated. Being water resistant, it finds use in the manufacture of water proofing materials. More than 35 000 rubber-based

products such as hand gloves, toys, balloons, hoses, footwear, etc. are manufactured. Besides, rubber is also useful in soil stabilization, in vibration absorption, road surfacing, etc.

1.4 Traditional Breeding

The global consumption of natural rubber is steadily increasing and the production has also to be increased so as to meet the demand. The major objective of rubber tree breeding is to develop potential clones with high rubber yield combined with desirable secondary characters such as high initial vigor, smooth and thick bark with good latex vessel system, good bark renewal, high growth rate after initiation of latex harvest, tolerance to major diseases and wind, etc. (Annamma *et al.*, 1990; Varghese *et al.*, 1992). Recently, importance has also been given to develop clones with tolerance to abiotic stresses such as drought, high temperature, cold, etc. (Thulaseedharan *et al.*, 2000). Clones attaining early tapping girth and high initial yields are preferred to clones with higher yields in a later stage (Lim *et al.*, 1973). In countries where labor is cheap and the small-holding sector is predominant, clones capable of withstanding high tapping intensities are preferred. Besides high rubber yield, superior technological properties of rubber, timber and its quality (latex–timber clones), and low incidence of tapping panel dryness (TPD) are also major breeding objectives.

The conventional methods of genetic improvement are introduction, selection, and hybridization. The elite clones developed in one country are introduced to other countries. Popular clones introduced from other countries are evaluated under local agroclimatic conditions and the promising ones are recommended for large-scale planting. Introductions are effected under bilateral and multilateral clone exchange programs. Considerable yield variability in seedling populations was first observed by the Dutch workers in Java and Sumatra in the second decade of the last century (Whitby, 1919). Simultaneously, the technique of bud grafting was perfected, which facilitated the fixation of desired characters and the development of early primary clones through ortet selection. Ortet selection, mother tree selection or plus tree selection, is the oldest selection method

adopted in rubber trees. Ortet is, therefore, the original tree from which members of clone have descended. Hybridization programs are aimed at combining genes for desirable characters found dispersed in different clones. Hand-pollination between selected parent clones, evaluation of F_1 hybrids, selection of promising recombinants from the progeny, and multiplication by bud grafting are still the most important methods of conventional breeding (Varghese and Maydin, 2000).

Rapid progress made in the ortet selection between 1919 and 1926 in Indonesia and Malaysia resulted in the development of many classical primary clones commercially very promising (Marattukalam *et al.*, 1980). Controlled pollination was started in 1918 in Malaysia, 1920 in Sumatra, 1937 in Brazil, 1939 in Sri Lanka, 1948 in China, and 1954 in India, using the primary clones developed through ortet selection. Progress in yield improvement in rubber tree resulted in gradual increment, from 650 kg ha^{-1} in unselected seedlings during 1920s to 1600 kg ha^{-1} in the best clones during the 1950s. The yielding potential was further enhanced to 2500 kg ha^{-1} in PB, RRIM, RRII, RRIC, IRCA, BPM, and RRIV clones during 1990s. During these 70 years of rigorous breeding and selection, notable clones including RRIM 501, RRIM 600, RRIM 712, PB 217, PB235, PB 260, RRII 105, RRIC 100, IRCA 18, IRCA 230, IRCA 331, and BPM 24 were derived (Tan, 1987; Simmonds, 1989; Clement-Demangne *et al.*, 2001; Priyadarshan, 2003). Some of the primary clones, like PB 86, Tjir 1, Pil D65, Gl 1, PB 6/9, and PB 86, selected during the aforesaid period, became parents of improved clones. It must also be acknowledged that primary clones like GT 1 and PR 107 are still widely used, although their identification traces back to the 1920s.

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

As a perennial tree species, genetic improvement through conventional breeding in rubber tree is rather a slow and difficult process. The major constraints in rubber tree breeding are long juvenile period, seasonal flowering, lack of any early selection parameters especially for estimating traits such as latex yield, susceptibility to TPD and wind damage, low fruit set, very long period of field

experimentation, and pronounced interaction of genotype and environment. The major advantages are monoecious nature of the tree, which makes hybridization easy and the amenability to vegetative method of propagation (Saraswathyamma, 2002). The recent developments in recombinant-DNA and *in vitro* plant regeneration techniques could provide a direct route for the introduction of specific genes controlling agronomic traits into crop plants. The transfer of selected genes in a single generation by genetic transformation is especially interesting for this species, since its improvement is limited by long breeding cycles and high levels of heterozygosity. The major objectives of genetic transformation of rubber tree in different laboratories are (a) improvement of agronomic traits of elite rubber clones and (b) production of pharmaceuticals and other valuable recombinant proteins in the transgenic rubber tree. In the improvement of agronomic traits, the underlying direction is toward development of transgenic rubber tree with increased rubber biosynthesis, improved quality and volume of timber, tolerance to various diseases as well as abiotic stresses, etc. (Thulaseedharan, 2002; Yeang, 2004). A unique feature of rubber tree is the presence of latex vessels with the continuous production and harvesting of latex, which contains about 30–40% rubber and remaining with a serum containing all the machinery for protein synthesis, provided the gene is integrated through transgenic technology. Hence, the rubber tree could be exploited as a biological factory for the production of desired recombinant proteins by the integration of the desired genes.

2. PROGRESS IN THE GENETIC TRANSFORMATION OF RUBBER TREES

2.1 Donor Genes Employed and Design of Transgenics

2.1.1 Marker and antibiotic selection genes

In spite of the economic importance of the rubber trees, transgenic approaches for crop improvement have started only a little more than a decade ago. Two major factors that helped to lay the foundation for modern plant biotechnology are the capacity to regenerate whole plants from single

cells without changing the original genetic features of the cell (Birch, 1997) and successful gene transfer into plant genomes with stable expression of an introduced foreign gene (Zambryski *et al.*, 1983) through the natural genetic transformation mechanism by *Agrobacterium tumefaciens*. The first transgenic rubber tree was developed in 1994 incorporated with *GUS* (β -glucuronidase) gene (Arokiaraj *et al.*, 1994). Rubber plants being very recalcitrant and rubber cultivation being restricted to specific locations around the world, only few laboratories are actively involved in rubber research. A list of genes successfully tried for rubber tree transformation is presented in Table 1. In order to optimize the *Agrobacterium*- and biolistic-mediated genetic transformation systems in rubber trees, different workers employed *GUS* as the marker gene (Arokiaraj *et al.*, 1994, 1996, 1998; Montoro *et al.*, 2000, 2003; Blanc *et al.*, 2006). The *GUS* gene used is from *Escherichia coli* and the expression is controlled by the cauliflower mosaic virus (CaMV) 35S promoter and the selectable marker gene used was the sequence coding for neomycin phosphotransferase II (*nptII*).

2.1.2 Genes for recombinant protein production

The advent of genetic engineering in the early 1970s and its application to plant biotechnology

have revolutionized agriculture. Recent years have seen a dramatic increase in application of biotechnology for the production of a variety of recombinant proteins in plants. Transgenic rubber trees that secrete human serum albumin (HSA) in the serum fraction of rubber latex were generated by Arokiaraj and coworkers in 2002. They constructed a binary vector pLGMR, which contained a 1.8-kb polymerase chain reaction (PCR)-amplified sequence coding for HSA fused with the CaMV 35S promoter and polyA tail to control the expression. *nptII* gene complementary DNA (cDNA) under the control of *nos* (nopaline synthase) 5' promoter and *nos* 3' polyA tail were used as the antibiotic selection. Further, Yeang *et al.* (2002) reported the expression of a functional recombinant antibody fragment in the latex of transgenic rubber. The binary vector used for the genetic transformation contained the gene for a mature immunoglobulin single chain variable fragment (ScFv) with specificity for the dental bacterium *Streptococcus gordonii*, together with the coding region of the tobacco pathogenesis-related protein signal sequence for targeting the recombinant fragment antibody. The CaMV 35S promoter and the *nos* terminator sequence were used for the expression of the gene. *nptII* gene was used as the selectable marker gene. Kala *et al.* (2006) used a cDNA sequence coding for a 10.8-kDa (kilodalton) TB antigen protein isolated from *Mycobacterium tuberculosis*.

2.1.3 Genes for tolerance to stress and TPD

Transgenic breeding for tolerance against environmental stress as well as TPD were initiated at the Rubber Research Institute of India (RRII). Transgenic rubber plants were developed using the functional gene coding for superoxide dismutase (Jayashree *et al.*, 2003). The 702 nucleotide rubber (*H. brasiliensis*) superoxide dismutase (Hb.SOD) cDNA was obtained by the reverse transcription PCR from the mRNA (messenger-RNA) isolated from the bark tissues of the trunk region, using forward and reverse sequences corresponding to a previously reported sequence of Hb.SOD (Mia and Gaynor, 1993). The Hb.SOD coding sequence was inserted into the binary vector pDU92.3103 (Tao *et al.*, 1995) at the unique *Bam*HI site between the CaMV 35S promoter and 3' polyadenylation sequences, thereby creating the binary vector pDU96.2144 (Jayashree *et al.*, 2003). Similarly, *SOD* gene containing binary vector were developed under the control of figwort mosaic virus (FMV) 34S promoter and transgenic plants were obtained (Sobha *et al.*, 2003a). Rekha *et al.* (2006) reported genetic transformation of rubber tree with *SOD* gene in the antisense orientation in order to understand the role of *SOD* in the normal growth and development as well as environmental stress tolerance, including TPD in rubber. In order to enhance the cytokinin level in the bark to confer tolerance against TPD, attempts were also made to develop transgenic plants integrated with gene coding for isopentenyl transferase (*ipt*). The plasmid vector used was pDU.970612, which contained the sequence coding for *ipt* from *Agrobacterium* under the control of its own 5' promoter and 3' polyadenylation signal (Kala *et al.*, 2003).

2.2 Status of Genetic Transformation in Rubber Trees

2.2.1 Optimization of transformation techniques

The possibility of genetic transformation in rubber trees was first explored by Arokiaraj and Rahaman (1991). They employed co-cultivation of *in vitro*- and *in vivo*-propagated plantlets with *A. tumefaciens* (Strain 541) and cultured

in the Murashige and Skoog (MS) medium without growth regulators. Co-cultivated explants developed tumors and produced octopine indicating effective transformation. Subsequently transformations were developed for direct DNA delivery through microprojectile bombardment as well as through *A. tumefaciens*-mediated methods (Arokiaraj *et al.*, 1994, 1996). In their studies, anther-derived calli were used as explants and binary vectors harboring *GUS* as reporter gene and either *nptII* or chloramphenicol acetyl transferase (*CAT*) as the selection gene. Genetic transformation was confirmed by histochemical staining and fluorometric assay for GUS activity, ELISA (enzyme-linked immunosorbent assay) for detecting expression of the *nptII* gene, and direct enzyme assay for detection of *CAT* gene expression were carried out. The presence of foreign gene in the transformed calli, embryoids and transgenic plants was further confirmed by PCR analysis. Arokiaraj *et al.* (1998) studied the constitutive promoter (CaMV 35S) directed β -glucuronidase expression in the laticifer system of transgenic rubber and the stability of expression of the transgene in successive vegetative generation raised through bud grafting of the original transformants. Anther calli were genetically transformed using *Agrobacterium* strain GV2260 harboring the β -glucuronidase (*uidA*) and *nptII* genes. β -glucuronidase protein was expressed in the leaves of transformed plants. GUS was also expressed in the serum fraction of latex. Transverse sections of the leaf petiole from a transformed plant revealed GUS expression, especially an enhanced expression in the phloem and laticifers. GUS expression was detected in three successive vegetative cycles propagated from the original transformants.

Studies were also undertaken to enhance the efficiency of *Agrobacterium*-mediated genetic transformation of rubber callus. It is reported that the virulence capacity of the *Agrobacterium* strain and the combination of the *Agrobacterium* strain and the type of binary vector used significantly influenced the transient expression of the GUS (Montoro *et al.*, 2000). Out of the five *A. tumefaciens* strains, C58pMP90, C58 pGV2260, AGL1, LB4404, and EHA 105 and the two binary vectors, pGIN and pCAMBIA 2301 tested the combination of EHA 105 and the binary plasmid vector pCAMBIA 2301 showed the highest transient expression. It is also reported

that transfer of friable callus from a maintenance medium containing 9.0 mM CaCl_2 to a calcium-free medium before *Agrobacterium* infection as well as use of a calcium-free *Agrobacterium* resuspension medium to inoculate friable calli significantly enhanced the transformation efficiency. Paramomycin was proved more effective than kanamycin for the selection of transformed cells (Montoro *et al.*, 2003). The influence of cryopreservation of explants, co-cultivation temperature, and duration of co-cultivation of the *Agrobacterium*-mediated genetic transformation of rubber callus was studied by the above group. It is reported that, the transformation efficiency and competence of the embryogenic calli were improved after two cycles of cryopreservation. When the co-cultivation temperature was reduced from 27 °C to 20 °C and the duration of this phase was increased up to 7 days, the GUS activity was increased (Blanc *et al.*, 2006).

2.2.2 Development of transgenic plants for environmental stress tolerance

After developing efficient plant regeneration protocols through somatic embryogenesis, RRII has initiated active research for the development of transgenic plants integrated with genes for desirable agronomic traits. An efficient *Agrobacterium*-mediated genetic transformation system for transgenic plant regeneration has been developed in the recent past (Jayashree *et al.*, 2000, 2003; Sobha *et al.*, 2003b). Initial focus was to develop transgenic plants tolerant to abiotic stresses like elevated light and temperature, drought, and TPD. In nature, plants encounter a wide range of environmental stresses that detrimentally affect their growth and development. Plants exposed to environmental stress generate excess reactive oxygen species (ROS) such as superoxide (O_2^-), hydrogen peroxide (H_2O_2) and hydroxyl radicals (OH^-) (Asada and Takahashi, 1987). Superoxide dismutase (SOD) is the first enzyme involved in the detoxifying process of reactive oxygen species (Fridovich, 1986). Significant yield loss occurred in plantations across the rubber-growing countries due to TPD, a physiological disorder, characterized by the browning of bark followed by the cessation of latex flow. Since, no pathogens are unequivocally proved as the causative organism yet, this is considered

as a physiological disorder. It is reported that the TPD-affected bark shows an increased free radical accumulation and a reduced level of SOD enzyme as well as cytokinin (Das *et al.*, 1998). Therefore, attempts were made at RRII to develop transgenic rubber plants tolerant to a variety of environmental stresses as well as TPD, by incorporation of the genes coding for SOD and *ipt*.

Agrobacterium-mediated genetic transformation was carried out with *Hb.SOD* gene under the control of CaMV 35S promoter. Two-month-old immature anther calli were used as the initial explants in the transformation experiments. The plasmid used was pDU96.2144, which contains *uidA* as the reporter gene and *nptII* as the selectable marker gene. Transgenic plants integrated with the SOD gene under the control of different promoters such as CaMV 35S and FMV 34S were developed separately from different cell lines obtained through independent transformation events. The stable integration and copy number of the transgene were confirmed through molecular analysis (Jayashree *et al.*, 2000, 2003; Sobha *et al.*, 2003a). The preliminary biochemical studies conducted with SOD-transformed callus cultures showed enhanced activity of SOD and related enzymes such as catalase and peroxidase (Sobha *et al.*, 2003b).

Genetic transformation with *ipt* gene for the overproduction of cytokinin was also attempted. Rubber (Clone RRII 105) anther calli were transformed through *A. tumefaciens* (strain EHA 105) harboring the binary vector carrying the gene coding for *nptII* as the selectable marker gene, *GUS* as the reporter gene, and the sequence coding for *ipt*. The putatively transformed calli were able to grow hormone autotrophically and showed increased cytokinin levels compared with the controls. The embryos showed developmental abnormalities and most of the transformants were severely deformed. The constitutive expression of *ipt* gene by its promoter elevated the endogenous cytokinin levels, which might have enhanced ethylene production leading to phenotypic abnormalities hampering the plant development (Kala *et al.*, 2003).

2.2.3 Transgenic plants for enhanced rubber biosynthesis

Natural rubber is cis-1,4-polyisoprene. The biosynthesis of rubber from sucrose is through a

series of reactions catalyzed by various enzymes. Few enzymes involved in the conversion of acetate into rubber in rubber tree latex have been analyzed, which indicates that the activity of 3-hydroxy-3-methyl glutaryl Coenzyme A reductase (*hmgr1*) is low compared to the other enzymes (Lynen, 1969) suggesting that the constitutive level of this enzyme may be a limiting factor in rubber biosynthesis. Arokiaraj *et al.* (1995) overexpressed *hmgr1* in transgenic rubber, where HMGR activities of transformed anther derived callus ranged from 70 to 410% of the value of wild-type control and the activity in the transformed embryos ranged from 250 to 300%.

In order to enhance the rubber biosynthesis, experiments were initiated at RRII to develop transgenic plants integrated with the genes coding for important enzymes involved in this pathway. Initially, the genes coding for *hmgr1*, farnesyl-diphosphate synthase (FDP) and rubber elongation factor (REF) were selected. The *hmgr1* and *REF* genes were cloned into the binary vector pBIB 121 for the genetic transformation which contains the antibiotic genes *nptII* and *hpt* (hygromycin phosphotransferase). The *FDP* gene was cloned into the binary vector pCAMBIA under the control of CaMV 35S promoter. Three *Agrobacterium* strains such as EHA 105, LBA 4404, and pGV 3101 were used for infecting the tissue for the transformation of *hmgr1* gene while EHA 105 alone is used for *FDP* and *REF* genes. Two-month-old calli were infected with different *Agrobacterium* strains carrying the above genes and the transgenic lines were selected. Transgenic embryos and few plantlets integrated with the *FDP* gene were regenerated. Further work in this direction is in progress at RRII.

2.2.4 Transgenic plants for recombinant protein production

For commercial production of diagnostic and therapeutic products, the pharmaceutical industry essentially depends upon microorganisms involving sophisticated bioreactors. Since plants are easy to maintain, require only sunlight, water, and agricultural inputs, they are cheaper compared to microorganisms involving bioreactors. As protein-manufacturing factories, they are also ecologically friendly. Production of diagnostic and therapeutic

products using plant biotechnology has become well recognized in the field of pharmaceutical industry. Recently, various recombinant proteins have been expressed in crop plants making them living factories for the production of commercially valuable proteins (Nilesh *et al.*, 2004).

Natural rubber from rubber tree is continuously extracted through tapping. The rubber tree has many unique advantages for biopharming. Rubber tapping is a systematic and controlled wounding of the bark. The bark of the rubber tree contains a complex network of articulated laticifers or latex vessels, notably in the soft bark of the trunk from which rubber is collected. The latex is a cytoplasm that contains rubber particles, microvacuoles known as lutoids, and double-membraned organelles rich in carotenoids assimilated to plastids, the Frey-Wysling particles (Paradkooper, 1989). All the organelles of nonphotosynthetic plant cells: vacuoles (the lutoids), plastids, mitochondria, nuclei, and endoplasmic reticulum are also present (de Faiy *et al.*, 1989). It also contains various types of RNAs (Priyadarshan and Clemant-Demange, 2004), polysomes, and ribosomes as well as other ingredients required for the protein synthesis. It means latex contains all the machinery for the protein synthesis, if the desired gene is inserted into rubber plants.

The disadvantage of plants in general as biological factories for recombinant protein production is that the proteins may be accumulated in certain plant portions and the harvesting is mainly by destructive methods. After each harvest, it takes time for new growth to take place before the next harvest, making the harvest batchwise, rather than continuous processes. The ideal plant for recombinant protein production would be one that is cheaper to maintain and easy to multiply clonally, while allowing for continual harvesting of the protein (Arokiaraj, 2000). In rubber tree, latex harvesting is by nondestructive method and a continuous process (every alternate days or once in 3 days) throughout the year and the latex replenishment after each tapping is rapid. Moreover, once the tree is genetically transformed, the trait could be fixed in the T₁ generation itself with large-scale clonal propagation. Therefore, among the plants, rubber tree is having the unique advantage as the most suitable candidate for biopharming.

The expression of a recombinant protein, the HSA in the transgenic rubber tree was reported

for the first time by Arokiaraj *et al.* (2002b). An attempt was made to express the 68-kDa HSA protein in transgenic rubber. Transgenic rubber plants that secrete HSA in the serum fraction of rubber latex were generated using a binary vector pLGMR.HSA (13.8 kb) containing HSA cDNA (1.8 kb) with its native leader sequence in the *A. tumefaciens* (GV2260) containing a supervirulent plasmid (pToK 47). In this vector (pLGMR.HSA), the inserted HSA cDNA with its leader sequence is placed under the control of a CaMV 35S promoter. Rubber anther callus (clone GL1) was used as the explant for the infection using *Agrobacterium* GV2260. The presence of the inserted gene was confirmed by PCR using the primers of *nptII* and HSA. Detection of HSA in the leaf and latex extracts was carried out using an antibody coupled to a protein chip array. Western blot analysis was also done for the immuno detection of the HSA. An expression level in the latex serum of about 24 µg of HSA per milliliter of latex extract in young plants was also detected.

Yeang (2004) reported the expression of a functional recombinant antibody fragment in the latex of transgenic rubber. The plasmid for the genetic transformation contained the gene for a mouse immunoglobulin ScFv with specificity for the dental bacterium *Streptococcus gordonii*. The CaMV 35S promoter and the *nos* terminator regulatory sequences and the selectable marker *nptII*, together with the coding region of the tobacco pathogenesis-related protein pathogenesis related protein 1a (PR-1a) signal sequence regulated the expression of the recombinant antibody fragment. The gene construct was transformed into *A. tumefaciens* (GV 2850). The presence of the inserted genes in the putative transgenic plants was analyzed by PCR. The ScFv protein concentration detected in the latex was about 6 µg ml⁻¹ latex serum for the most productive plant.

Recently, attempts were initiated at RRII for the production of a recombinant TB antigen protein in rubber. The embryogenic calli derived from the leaf explants were transformed with the *A. tumefaciens* strain LB 4404 carrying the binary plasmid vector having the gene coding for a 10-kDa TB antigen and the *nptII* as the selectable marker gene under the control of CaMV 35S promoter. Co-cultivated tissues were transferred onto a selection medium containing kanamycin (350 mg l⁻¹) and cefotaxime (500 mg l⁻¹). High-

frequency transformation was obtained and embryos were developed from the transgenic tissues on the modified MS medium with benzylamino purine (BA) (2.0 mg l⁻¹), gibberellic acid A3 (GA3) (1.2 mg l⁻¹), α-naphthalene acetic acid (NAA) (0.2 mg l⁻¹) and 2,4-dichlorophenoxyacetic acid (2,4-D) (0.1 mg l⁻¹). The gene integration was confirmed by PCR analysis. Work is in progress to develop plantlets (Kala *et al.*, 2006).

2.3 Methods of Genetic Transformation

Genetic transformation is a potential tool in different areas such as manipulation and understanding of the biochemical processes, knowledge of genome regulation, and integration of the genes, which is not feasible through conventional breeding. Different techniques for gene transfer into plant systems have been developed, which includes *A. tumefaciens*- and *A. rhizogenes*-mediated transformation, microprojectile bombardment, tissue and protoplast electroporation, polyethylene glycol (PEG)-mediated direct gene transfer to protoplasts, microinjection, and fiber-mediated transformation. The possibility of genetic transformation in rubber tree was first explored in 1991 by *A. tumefaciens*-mediated transformation of callus derived from *in vitro* and *in vivo* seedling cultures (Arokiaraj and Rahaman, 1991). The first transgenic rubber plant was produced by the integration of *GUS* and *nptII* genes into callus cultures by particle gun method. However, because of the efficiency and convenience, *A. tumefaciens*-mediated genetic transformation system remains as the most widely used method for rubber genetic transformation.

2.3.1 *Agrobacterium*-mediated gene transfer in rubber trees

2.3.1.1 *A. tumefaciens*—a natural vector

The natural capacity of the gram-negative soil bacterium, *A. tumefaciens* to introduce a segment of oncogenic DNA present in the tumor-inducing (Ti) plasmid makes it an efficient vector system in genetic transformation. In rubber, *Agrobacterium*-mediated genetic transformation has been used widely and effectively for genetic transformation

(Arokiaraj *et al.*, 1996, 1998; Jayashree *et al.*, 2003; Sobha *et al.*, 2003a; Kala *et al.*, 2003). Strains of *Agrobacterium* used commonly for transformation include C58, EHA101, EHA 105, LBA 4404, pGV2260, and pGV3850. These have been reported to show high efficiency in rubber genetic transformation. Presence of phenolic compounds in rubber cells might have contributed to the success of *Agrobacterium*-mediated transformation since this act as *vir* gene inducers aiding in transfer-DNA (T-DNA) transfer. In most of the reports on rubber genetic transformation using *Agrobacterium*, *nptII* has been used as the selection marker and qualitative marker is the commonly used GUS reporter. In recent reports on transformation, most vectors were found to avoid the qualitative markers since these were found to hamper plant regeneration.

2.3.1.2 *Agrobacterium* protocols

A detailed protocol of *Agrobacterium*-mediated genetic transformation developed at the RRII is described here (Figure 2). *Agrobacterium* strain EHA 101 was transformed with the binary vector pDU 96.2144, which contained *uidA* as the reporter gene, *nptII* as the selectable marker gene, and the 702-nucleotide *Hb.SOD* cDNA under the control of CaMV 35S promoter (Jayashree *et al.*, 2003). *Hb.SOD* gene under the control of FMV 34S promoter were also tried separately (Sobha *et al.*, 2003a). The bacteria harboring the vector was grown in the AELB medium overnight at 28°C in the presence of 50 mg l⁻¹ kanamycin and 20 mg l⁻¹ gentamycin until an A₆₀₀ of 0.5. The bacterial cell density was adjusted to 5 × 10⁸ cells ml⁻¹ in this medium and used for tissue infection.

Approximately 2.0 g of calli were precultured on a callus proliferation medium prior to infection with *Agrobacterium*. The explants were immersed in the *Agrobacterium* cultures for 10 min and were blotted dry in a sterile filter paper and transferred to a co-cultivation medium (MS + acetosyringone 20 mg l⁻¹ + glycine betaine-HCl 153.6 mg l⁻¹ + proline 113 mg l⁻¹). After 3 days of co-culture the explants were subcultured on a selection medium containing 500 mg l⁻¹ cefotaxime and 300 mg l⁻¹ kanamycin for 50 days and maintained at 25 ± 2°C in the dark. After 8 weeks of

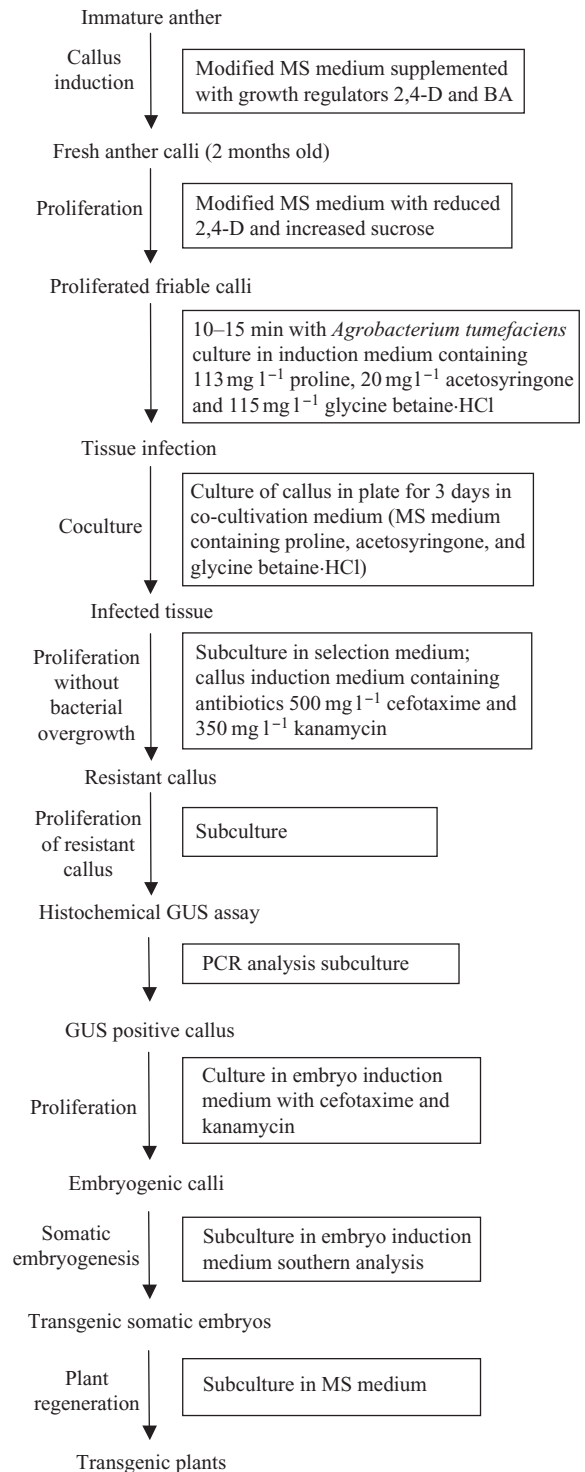

Figure 2 Flow chart of *Agrobacterium*-mediated genetic transformation and plant regeneration protocol in rubber

culture, kanamycin-resistant callus lines were subjected to histochemical GUS assay according to Jefferson (1987). The transformed cells were incubated overnight at 37°C in 2 mm X-gluc (5-bromo-4-chloro-3-indolyl β -D glucuronide) in phosphate buffer (pH 7.0) containing 10 mM EDTA, 0.5 mM potassium ferricyanide, 0.5 mM potassium ferrocyanide, and 0.1% (v/v) Triton X-100, and were observed under microscope.

The transformed callus lines were subcultured into a fresh medium for proliferation. After 2 months of culture, the embryogenic calli obtained were subcultured to an embryo-induction medium. The gene integration in the transgenic plants was confirmed by PCR analysis and Southern hybridization. The different hybridization patterns obtained for the transgenic plants indicate random integration and multiple insertions of the T-DNA in the genome of the plants.

In order to understand the effect of the physiological state and sources of explants on transformation efficiency, Rekha *et al.* (2006) examined six different explants, i.e., intact explants (immature anther, ovule), 2-month-old callus and embryogenic callus of the anther and ovule for *Agrobacterium* infection. Results suggested that the target tissue is one of the important factors that determine the transformation efficiency. Among the different explants used, maximum transformation frequency (62%) was obtained with the embryogenic callus of the anther. Similar results were also observed when embryogenic callus derived from leaf explants was used for *Agrobacterium* infection (Kala *et al.*, 2006). A detailed investigation has been carried out by Montoro *et al.* (2000) on the effect of exogenous calcium on *Agrobacterium*-mediated gene transfer in rubber friable callus. It is demonstrated that the exogenous CaCl_2 reduces the efficiency of *Agrobacterium*-mediated gene transfer. The use of Ca-free media, both in bacteria and plant tissue preparations, dramatically increased the number of transformation events and consequently the positive effect of acetosyringone on transformation efficiency. Further, this group has done extensive studies to improve the transformation efficiency by manipulating the competence of the explants and the co-cultivation temperature (Blanc *et al.*, 2006). They observed a drop in transformation efficiency as the age of callus increases. Reducing the temperature and lengthening

the co-cultivation period with the *Agrobacterium* suspension increased the transformation frequency significantly. Rattana *et al.* (2000) reported that co-cultivation at 20°C slowed down the *Agrobacterium* proliferation and callus browning by which duration of co-cultivation could be extended. In that way, contact between the plant cells and the bacteria was favored, making gene transfer more efficient (Blanc *et al.*, 2006).

2.3.2 Biolistic transformation system

Gene delivery into intact tissues by DNA-coated microprojectiles allows genetic transformation of several recalcitrant species. Usually, this technique results in transient gene expression and chimera formation. Effective gene transfer using this system is found to be influenced by several factors. Nature and size of particles and target tissues usually influence gene expression. Biological factors such as growth stage and media supplements that help cell survival are also detrimental. Acceleration of a microcarrier was achieved by a shock wave generated from gunpowder charge or sudden release of compressed air. In rubber, this technique was used by Arokiaraj *et al.* (1994) for transforming anther-derived callus with vectors harboring the *gus* gene, *nptII*, and *cat* gene. Plasmid DNA was precipitated on to tungsten particles, loaded on to a microprojectile, and accelerated toward the target placed 5 cm below the stopping plate with a biolistic particle gun. The calli were then dark incubated for 24 h after which they were transferred to the incubation medium containing antibiotics from which kanamycin-resistant transformants were obtained. Optimization of parameters that would influence DNA delivery such as microprojectile velocity, coating mixture, and particle dispersal were carried out, which proved that microprojectiles can deliver DNA into rubber cells and helped recovery of kanamycin-resistant transformants.

2.4 Regeneration of Whole Plant

An efficient plant regeneration pathway through somatic embryogenesis is an essential prerequisite for crop improvement through transgenic approaches besides using this as a micropropagation

system (Thulaseedaran *et al.*, 2004). Wang *et al.* (1980) and Wan *et al.* (1982) successfully regenerated rubber plants through somatic embryogenesis from anther walls. Carron (1981) used inner integument tissue of seeds for somatic embryogenesis and was successful in plantlet development. Extensive experiments were carried out by many researchers to enhance the frequency of somatic embryo induction and plant regeneration. Studies were also conducted to optimize cultural conditions, nutritional and hormonal requirements during somatic embryogenesis. The parameters include the effect of polyamines (El Hadrami *et al.*, 1989), hormone balance (Michaux-Ferriere and Carron, 1989), water status of the medium and explant (Etienne *et al.*, 1991a), mineral and carbohydrate nutrition (Etienne *et al.*, 1991b), interaction of growth regulators, sucrose, and calcium on callus friability (Montoro *et al.*, 1993, 1995), role of sucrose and ABA on embryo induction (Veisseire *et al.*, 1994a, b; Cailloux *et al.*, 1996; Linossier *et al.*, 1997), and carbohydrate types (Blanc *et al.*, 2002). In spite of all these studies, the plant regeneration frequency remains very low. In most of the above studies inner integument tissue was used as the explant. It is reported that the calli obtained from the integuments of immature seeds frequently display browning leading to tissue degeneration and a loss of embryogenic competence (Housti *et al.*, 1991).

There has been a renewed interest in rubber for development of techniques for plant regeneration through somatic embryogenesis especially for use in genetic transformation (Kumarijayasree *et al.*, 1999). In order to identify the suitable explant source, a variety of explants such as leaf, tender shoots, integumental tissues of immature fruit, immature anther, immature inflorescence, etc., were tried at the RRII. Extensive optimization experiments were carried out to improve the plant regeneration efficiency through somatic embryogenesis for the Indian clones of rubber. Attempts were also made to standardize the optimum growth regulator concentration and the balance between different growth regulators, the nutritional requirements, and the physical factors such as light and temperature for maximum callus proliferation, embryo induction, and subsequent regeneration of normal and healthy plantlets. As a result, initially immature anthers (before microsporogenesis) (Kumarijayasree *et al.*, 1999),

immature inflorescence (Sushamakumari *et al.*, 2000) and leaf (Kala *et al.*, 2005, 2006) were identified as suitable explant source and protocols were developed for high-frequency somatic embryo induction and plant regeneration for RRII-105, the most popular Indian rubber clone. Kumarijayasree *et al.* (1999) reported a standardized protocol for the induction of friable embryogenic callus, somatic embryogenesis, and further plant regeneration from the immature anthers. Optimum callus induction was obtained in the modified MS medium supplemented with 2.0 mg l^{-1} 2,4-D and 0.5 mg l^{-1} kinetin. Somatic embryo induction was found to be better with 0.7 mg l^{-1} kinetin and 0.2 mg l^{-1} NAA. Further development of the embryos into plantlets was achieved on a hormone-free medium (Figure 3).

Culture conditions and other nutritional requirements for improving the efficiency of somatic embryo induction and germination were investigated by Kumarijayasree *et al.* (2001). Immature anthers precultured in a liquid medium for 10 days followed by 25-day culture in a solid medium were found to promote callus induction. The embryo induction efficiency was promoted by supplementing 200 mg l^{-1} glutamine and 400 mg l^{-1} casein hydrolysate in the embryo-induction medium. Dark incubation favored callus induction and proliferation as well as induction of embryogenesis, whereas plantlet regeneration was found to be light dependent. A study on the gibberellic acid requirement on embryo induction and maturation revealed that incorporation of GA3 up to 2.0 mg l^{-1} increased the embryo-induction frequency. Germination percentage was also significantly enhanced by higher concentrations; however, further plant development was affected by increasing GA3 levels (Kumarijayasree and Thulaseedharan, 2004). A detailed investigation was also done on the response of various cytokinins such as BA, zeatin (ZEA), kinetin and thidiazuron (TDZ) on germination of somatic embryos derived from immature anther explants. TDZ was proved to be superior to BA and ZEA while kinetin showed the least response. Maximum percentage of embryo germination and plantlet regeneration was 80% and 82%, respectively, when the medium was supplemented with TDZ (Kumarijayasree and Thulaseedharan, 2005).

Sushamakumari *et al.* (2000) studied the role of sucrose and abscisic acid (ABA) on embryogenesis

Figure 3 Somatic embryogenesis and whole plant regeneration from immature anther explants of *H. brasiliensis* (RRII 105 clone): (a) embryogenic callus; (b) globular embryos; (c) bipolar embryos; (d) full-plantlet development; and (e) somatic embryo-derived plants were established in poly bags and ready for field planting

from immature inflorescence-derived explants. A higher sucrose level was found to be essential for effective embryo induction as well as maturation. However, lower level was found to be beneficial for plant regeneration. Further, efforts have been made to enhance the embryo induction and plant regeneration frequency by the manipulation of the nutrients and hormonal combinations. Recently a system was also standardized for plant regeneration from leaf tissues of rubber where the explants are available throughout the year. Callus induction could be obtained in the MS medium with enhanced calcium nitrate (850 mg l^{-1}) and supplemented with casein hydrolysate (1.0 mg l^{-1}), B₅ vitamins, sucrose 20 g l^{-1} , and phytohormones BA (1.0 mg l^{-1}), 2,4-D, (1.5 mg l^{-1}), and NAA (0.2 mg l^{-1}). Embryo induction was obtained in the modified MS medium by the addition of amino acids, glutamine (300 mg l^{-1}), proline (100 mg l^{-1}), and arginine (37 mg l^{-1}), and organic supplements like casein hydrolysate and coconut water with phytohormones, 2.0 mg l^{-1} BA, 1.0 mg l^{-1} GA₃, 0.2 mg l^{-1} NAA and 0.1 mg l^{-1} 2,4-D. Maturation and apex induction of embryos could be obtained

in woody plant medium containing coconut water 10%, malt extract 100 mg l^{-1} , casein hydrolysate (400 mg l^{-1}) and hormones BA (0.3 mg l^{-1}) and GA₃ (1.2 mg l^{-1}). The hormone-free 1/2 MS medium helped plant regeneration (Figure 4). All media except callus induction needed the presence of activated charcoal (Kala *et al.*, 2005, 2006).

With minor modifications, the transgenic rubber callus integrated with different genes could be regenerated. At RRII protocol for the regeneration of transgenic plants integrated with the *SOD* gene under the control of different promoters were developed (Jayashree *et al.*, 2003; Sobha *et al.*, 2003a). The proliferation of the transgenic callus and embryo induction could be obtained as reported earlier (Kumarijayasree *et al.*, 1999). A combination of ABA (0.1 mg l^{-1}) and phytigel (0.4%) promoted the frequency of embryo induction. A high sucrose level was beneficial for both embryo induction as well as maturation in rubber. Addition of organic supplements and polyamines played a significant role in the induction and maturation of the embryos. Inclusion of spermine (2.0 mg l^{-1}) in the embryo-induction medium had

Figure 4 Somatic embryo induction and plant regeneration from leaf explants of RR11 105 clone of *H. brasiliensis*: (a) callus initiated from leaf explants; (b) embryogenic callus with embryos; (c) bipolar embryos; (d) development of full plants; and (e) a plantlet established in poly bag

a positive effect on embryogenesis. Although, casein hydrolysate (200 mg l^{-1}) was good for the embryo induction, maturation was favored by the addition of 150 mg l^{-1} banana powder. Addition of amino acids like glutamine and proline influenced the maturation frequency dramatically. Plant regeneration was promoted in the medium with reduced levels of sucrose (20 g l^{-1}) and phytagel (0.2%) (Figure 5).

3. FUTURE ROAD MAP

3.1 Expected Improved Products through Genetic Engineering

Biotechnology would play an important role in the future of the rubber industry. Conventional rubber breeding is a long process involving various methods such as selection of population followed by hybridization, progeny evaluation, and backcrossing. It takes more than 25 years to

release a new clone by using any of these methods. Rubber tree is a good candidate for transgenic manipulation due to the long breeding cycle and heterozygous nature. *In vitro* techniques including plant regeneration via somatic embryogenesis have been established in this tree species. Thus, the basic technology for genetic manipulation of rubber plant at the cellular and molecular levels is available, making rubber a suitable crop for genetic engineering. Many agronomic traits could be considered for a rubber biotechnology program, namely, high yield potential, tolerance to TPD, tolerance to environmental stresses and diseases, production of recombinant proteins, improvement in wood quality, etc.

3.1.1 Enhancement of latex yield in transgenic rubber trees

As in the case with most other crops, rubber biotechnology has focused much effort on

Figure 5 Development of *Hevea* transgenic plants for the overexpression of *Hb.SOD* gene using immature anther-derived callus as initial explants: (a) emergence of new transgenic callus lines on selection medium containing kanamycin (350 mg l^{-1}) and cefotaxime (500 mg l^{-1}); (b) globular embryos from transgenic callus; (c) putatively transformed bipolar embryos; (d) germination of transgenic plants; (e) PCR confirmation of transgenic plants using *nptII* gene-specific primers; (f) histochemical GUS expression analysis; and (g) transgenic plants growing in poly bags

increased latex yield. In any crop improvement program, the overall objective is to increase yield and adaptation to environmental conditions. To meet this objective, the genetic variation must be exploited by conventional breeding methods. The major limitation to crop improvement is likely to be the availability of germplasm from which desirable genes can be readily introgressed into the plant of interest. However, major improvements have been made over the last century in the productivity of rubber, as the yield of dry rubber per acre have been increased significantly by releasing better clones. There is no doubt that the conventional breeding will continue to increase the latex production in rubber trees, but a stage would eventually come when the rate of rubber biosynthesis with the tree becomes the limiting factor (Arokiaraj, 2000). At this stage, latex yield will be enhanced only by treatments designed to affect the rate of rubber biosynthesis. It was reported that the constitutive level of *hmgr1* enzyme may be a limiting factor

in rubber biosynthesis. On the basis of this hypothesis, Arokiaraj *et al.* (1995) initiated genetic transformation experiment to overexpress *hmgr1* in rubber, where *hmgr1* activity of transformed callus ranged from 70 to 410% more value of wild-type control and the activity in transformed embryos obtained ranged from 250 to 300%. However, they failed to produce transgenic plants. Among the latex associated proteins, the amount of REF in the whole latex is proportional to the rubber content (Priya *et al.*, 2006). As such, if REF protein amount is shown to be correlated simultaneously with rubber yield, there is a possibility that this relationship could be used to select for clones that are able to sustain high rubber biosynthetic efficiency. It could be possible to enhance rubber yield by overexpression of *REF* gene involved in rubber biosynthesis. At present, the authors' laboratory had undertaken a research project in which rubber biosynthesis genes such as *hmgr1*, *FDP*, *REF*, and *cis-prenyl transferase* were cloned into binary vectors and

transformation works are in progress to develop transgenic plants.

3.1.2 Transgenic plants for TPD tolerance

Plant stress is one of the major problems for crop production. In rubber tree, TPD syndrome is considered to be a physiological disorder, which greatly affects latex yield. Once the TPD occurs, the tapping incision is partly or entirely blocked and the amount of latex production is significantly decreased or stops completely. The incidence of TPD occurs in 12–50% of rubber trees in almost every rubber-planting country. Under normal conditions, active oxygen species (AOS) are efficiently scavenged by detoxifying enzymes such as SOD. Nevertheless, during TPD stress conditions this defense system becomes saturated and cellular damage is inevitable (Chrestin, 1989). The presence of excessive AOS results in severe latex yield losses. It has been reported that SOD activity protected plants from oxidative and other stresses. In order to overcome this TPD problem, an attempt was made to overexpress *SOD* gene in transgenic rubber plants. Transgenic rubber plants have been successfully developed and established in soil at the RRII (Jayashree *et al.*, 2003). Further evaluation is in progress.

3.1.3 Transgenic trees with improved wood quality

Until now, the most important product of the rubber tree was its latex and considerable efforts have been made to improve the latex yield. With the depletion of tropical forests leading to a shortage of timber for many industrial and engineering uses, attention has moved on rubber wood as an alternative source of timber for markets (Arokiaraj *et al.*, 2002b). As the composition of wood is important for the pulp industry, genetic engineering to modify lignin content in rubber is a very active area of research that has been stimulated in recent years by the characterization of important genes controlling lignification. The export of rubber wood from Malaysia rose from RM 900 million in 1993 to RM 3.7 billion in 1998 and subsequently to

RM 5.2 billion in 2001 (Arokiaraj *et al.*, 2002b). These figures clearly indicate how rubber wood industry is growing. For tree species, only limited information is available about the process of differentiation and development that are involved in wood formation. Knowledge of what determines the pathway of differentiation that cambium cells undergo is essential to any attempt to design better wood characteristics and improve latex yield. In rubber tree, the homeobox (*HB*) gene has been isolated and it is presumed that *HB* genes may be involved in differentiation of cambium cells to form latex vessels (Arokiaraj *et al.*, 2002b). Research in this direction is important because it clearly demonstrates that modifying specific genes in the wood-forming process can also potentially influence important tree characteristics and hence improve timber production.

3.1.4 Production of recombinant proteins in transgenic rubber plants

Currently, numerous immunotherapeutic proteins, antibodies, and vaccines have been produced. Recent work suggests that plants will be a facile and economic bioreactor for large-scale production of industrial and pharmaceutical recombinant proteins (Kusnadi *et al.*, 1997). Genetically engineered (transgenic) plants have several advantages as sources of proteins compared with human or animal fluids or tissues, recombinant microbes, transfected animal cell lines, or transgenic animals. These include the following: (1) efficiency of the transformation events at large scale; (2) correct assembly of multimeric antibodies (unlike bacteria); (3) increased safety, as plants do not act as hosts for human pathogens, such as human deficiency virus (HIV), prions, and hepatitis viruses; (4) production of raw materials on an agricultural scale at low cost; and (5) reduced capitalization costs relative to fermentation technology. Other than latex and timber, useful products such as serum proteins, sugars, lipids, carotenoids, inositols, organic acids, and minerals in the latex can be exploited profitably with a new research strategy. Commercial-scale production of recombinant proteins from rubber plants will also benefit from the technology and equipment

commonly used in the food and beverage industry. Already, HSA proteins were expressed in a transgenic rubber plant (Arokiaraj *et al.*, 2002b). Rubber trees synthesize enormous volume of latex upon tapping and the trees could be exploited without any destruction for large-scale production of the foreign protein throughout the year. Depending upon the promoters used, transgenic proteins will be sequestered throughout the plant or in specific parts of the plants or specific organelles within a given plant cell. A laticifer cell-specific hevein promoter has been reported earlier (Pujade-Renaud *et al.*, 2005). In this respect, the RR II has been working on isolation of laticiferous specific promoters, which will eventually enhance the recombinant protein production in transgenic rubber trees. Recently, laticiferous-specific promoter sequences for rubber elongation factor (Priya *et al.*, 2006), hevein (Saleena *et al.*, 2006), β -1,3-glucanase (AY325498), and hmgr1 (DQ785798) have been isolated and characterized. Further work is in progress to develop transgenic plants for recombinant protein production as well as for enhanced rubber production by inserting the appropriate genes under the control of laticifer cell-specific promoters.

3.2 Risks and Concerns

The introduction of transgenic crops into the existing natural system has generated a number of questions about possible negative consequences. The issues on transgenic plants can be of various groups of concerns as delineated below.

3.2.1 Damage to human health and natural environment

The possibility that we might see an increase in the number of allergenic reactions to food as a result of genetic engineering has a powerful emotional appeal. Since rubber is not used as food crop, there is no such food safety issue with transgenic rubber plants. Gene flow from transgenic crops to others requires the following: (1) the presence of sexually compatible wild relatives close to the crop; (2) an overlap of flowering times between

the crop and wild relatives and the presence of a pollinating agent such as a bird or an insect unless the likelihood that transgenes spread can be different for each crop and wild combination in different area of the world. If pollen grains from transgenic rubber plants are released in these areas they do not encounter any compatible plants to pollinate and therefore the risk of gene flow is remote. Also rubber-planting materials are developed via bud grafting, which further reduces the risk.

3.2.2 Concerns about damage to current farming practices

Hybridization of transgenic crops with nearby conventional crops raises concerns on several fronts. Movement of pollen from a transgenic field to a conventional field involves farmers in discussions about the distance required between fields to ensure purity of a crop, and about who must pay if unwanted genes move into a neighbor's crop. It will be important to ensure that hybridization is not occurring in the field. Many agencies publish recommended minimum isolation distances for a variety of crops. These distances have been decided to maintain a level of purity that has been acceptable to the agricultural community in the past. When there is a danger of gene flow to nearby fields, it is possible to prevent contamination of nearby crops by planting tall barrier plants to physically block the flow of pollen. If genetically modified (GM) pollen pollinates plants in neighboring field, then the issue of genetic trespass may arise. These issues have already prompted several lawsuits and they will continue to be a factor in the development and use of transgenic plants for years to come. As far as transgenic rubber plants are concerned, it takes about 6 years for first flowering, so the crop suitability can be assessed before pollen production. The main objective of rubber transformation is to produce plants for enhanced latex yield, TPD tolerance, disease resistance, and recombinant protein production. Also, the ultimate product from transgenic rubber plant is latex with protein and it is to be purified from latex, so neither the inserted gene nor the selection marker gene is thus available to the consumer.

3.3 Intellectual Property Rights for Transgenic Rubber Plants

The historical context of overincreasing protection for plant innovations, coupled with ongoing efforts to achieve international harmonization, provides an optimistic backdrop to some of the uncertainties that surround present efforts to obtain strong intellectual property protection for the full scope of innovations in the area of transgenic plants. An important objective of intellectual property law is to provide a reliable framework of rules, so that important commercial decisions about investigations in research may be made with a degree of certainty about how the products of the research will be protected. On the basis of this requirement for predictability, intellectual property laws are typically drafted in general terms and applied to new technology on the basis of established principles.

The requirements for patentability are generally judged with respect to the claimed invention. In addition, an invention must be within the categories of subject matter deemed patentable in a particular jurisdiction. There is also a generally recognized requirement that the description of an invention in a patent must be provided to allow a skilled technical person to make and use the invention, without the need for further innovation. Also a patentee is free to define the invention broadly in the claims and to cover various aspects of the invention, provided the requirements for patentability can be met with respect to each claimed aspect of the invention. To be new, an invention generally must not previously have been made available to the public, either through human activities or by virtue of its occurrence in nature. Many inventions are combinations of pre-existing knowledge in a way that yields an unexpected and hence patentable result. Typically, genetic inventions must be carefully characterized in claims in ways that distinguish them from a naturally occurring product. Genomic innovation in the field of transgenic plants may include genes that are novel in the sense that they have not previously been identified, genes that are novel only in the sense that their function has not previously been identified, new combinations of genetic material, such as a recombinant gene made up of a tissue-specific promoter, and a coding sequence with which it would not normally be associated

with expressed sequence tags. The exclusive right conferred by a patent in most jurisdictions includes the right to exclude others from making, using, and selling the invention defined by the claims for the term of the patent. Generally, patents have a term of 20 years from the filing date of the patent application. The innovation protectable under a plant patent can be seen as the combination of a three-step process: (a) cultivation or discovery of the plant, (b) identification of the new and distinct characteristics of the plant, and (c) asexual reproduction of the plant. Patents clearly offer the most flexible form of intellectual property protection for transgenic plants. Currently, RRII has undertaken various projects for development of transgenic plants and expected to produce soon. Once the transgenic plants are available then efforts will be taken to protect those transgenic plants intellectual property rights (IPR) by filing patent.

3.4 Public Perceptions of Transgenic Rubber Plants

Transgenic plants will continue to be developed and grown in the future, provided that a number of social and political constraints can be overcome. To understand public perceptions about transgenic plants, it is helpful to understand public perception of technology and educators have long been interested in how people perceive and understand risks associated with health and environmental issues (Wilson and Crouch, 1987). Risk perception must be considered in its social and cultural context. Many problems associated with risk management and communication result from the differences between scientists and the public (Freudenburg, 1988). The technical concept of risk is too narrow and ambiguous to serve as the crucial yardstick for policy making. Public perceptions, however, are the product of intuitive biases, economic interests, emotions, and cultural values. Technical risk must, therefore, be viewed in combination with psychological, social, and cultural processes that can heighten or reduce public perceptions of risk.

GM ingredients in food are perceived as more risky because they are considered to pose an involuntary risk. Many people believe they have very little control over food production

and processing. Furthermore, people are often concerned with secondary effects that the experts are unable to assess. Because political leaders have many of the same perceptions as other citizens, they are likely to base policy decisions on subjective factors as well. Public perception of risk is also influenced by public attitudes toward science and technology in general (Freudenburg, 1988). These problems are particularly serious as related to agriculture, because many people are no longer personally familiar with farming. Most have little understanding of how food is produced. If people are genuinely interested in a subject, such as biotechnology, they talk about it. The surveys in Europe, Canada, and the United States asked consumers to evaluate different applications of biotechnology (Hoban and Katic, 1998). The results are actually quite encouraging. The opponents of biotechnology in Europe have had the chance to tell their side of the story for several years without much balance. Educational efforts are starting to take hold among European leaders and consumers. Overall, we need to increase consumer understanding of food production and processing. However, the products from transgenic rubber plants are not consumed directly as food so there is no risk factor involved. Therefore, it could be easily explained to public how their understanding about transgenic rubber products.

3.5 Industry Perspectives

The success of GM organisms (GMOs) in the fresh-produce market in the world hinges on several factors: (1) the existence of a benefit from any GMO that is evident or can be made evident to the buyer; (2) the education of the buyer (whether a trade buyer or a consumer) about the development (process) and benefits of GMOs (this included the labeling debate); and (3) successful interaction with opponents of GMOs. The ultimate buyer is the consumer, but there are many buyers along every distribution chain. In the food business, seed companies buy materials they need to produce their seeds. Growers buy seeds and plants from the seed companies. Genetic engineering offers many potential benefits to the producer including the ability to grow a crop in hostile conditions, time savings, economic savings, economic gain, and environmental benefits. Where the growers see that

the benefit of a GMO is worth it, he will pay more for it: (1) genetically engineered drought resistance would allow production in hostile climates as well; (2) genetically engineered disease resistance can permit production in areas infested with a given disease and can reduce crop protection inputs, savings the grower money, time, and environmental impact; and (3) genetically engineered rubber plant for recombinant protein production would give additional income to the growers along with rubber.

Consumers may see some of the on-farm benefits as beneficial to society at large and a certain percentage of them might pay more for a product that can be grown with fewer crop protection chemicals. The produce industry, as any other industry, reacts to its customer's actual or potential desires. The desire for greater availability of produce led to breeding new clones that can be cultivated for high yield potential. Growers and researchers have worked to bring value-added products to the market place. Genetic engineering allows breeding to take a huge step toward specificity in trait exchange: whether the genetic enhancement benefited the industry or consumers, labeling was an issue. Labeling on the marketing side was something else entirely. It became a major consumer issue and any major consumer issue usually surfaces as a major trade issue. However, rubber is not consumed as food, so there is no such issue to the industry. When genetically engineered rubber trees are in the small-scale trial, it is quite possible that consumer issues may be discussed before entering into market.

3.6 Political and Economic Consequences

Biotechnology is increasingly affecting the competitive base for much of that industry. As with most revolutionary technological changes, biotechnology has generated both economic and political responses. The new technologies have fundamentally altered the innovation process itself. The advent of biotechnology did two things: first, it created the potential to target the research more finely to specific market needs; second, it made the research process far more complex, with no one individual or small group of individuals able to undertake the entire process. The fragmentation of the innovation system into different structures of knowledge development and

use has fundamentally affected the economics of scale and scope in the industry. Most of the fundamental patentable technologies developed have come from desperate research programs around the world and have then been assembled and commercialized by private companies. The introduction of biotechnology has also participated in a major industrial restructuring in the agrifood sector. The opportunity presented by biotechnology to manage the research process to deliver custom products has created investment potential for some private companies while creating a threat or risk to many existing business. However, rubber is produced mainly from a few Asian countries and then traded globally. As a result, there is increasing potential that traditional net exporters may both export and import. All these trends in economics of scale and scope, product attributes, and consumer demand increase the dependence of the industry on international trade. The fundamental economic changes underway in the rubber sector are creating both winners and losers. Economic studies done over the years show that research in rubber has yielded relatively high private returns and even higher public returns but that farmers tend to get a smaller share of the returns on innovations that improve yield rather than quality and their share is depressed when the related processing sector is imperfectly competitive.

Economic change often is precipitated by or compels political responses. This is especially true for changes in the rubber sector, which is traditionally viewed as a politically important constituency that produces a strategic rubber of value as a geopolitical tool. The most significant government response to the introduction of biotechnology was the extension of intellectual property rights to processes and products of biotechnology. Governments around the world have been urged to regulate biotechnology-based research and production. However, rubber biotechnology research is in the infant stage and it will take more time for practical reality to trigger political responses.

1. INTRODUCTION

Plants produce a wide variety of secondary metabolites that are used as pharmaceuticals, food additives, and industrial raw materials. Chemical synthesis has been successful for certain metabolites of plant origin, such as menthol. However, as most of these compounds have complex chemical structures and their bioactivities are critically defined by their chirality, chemical synthesis can require many complicated reaction steps, and the recovery rates are not always high, leading to high costs for the synthesis of these natural products. For these reasons, the extraction of useful secondary metabolites from medicinal plants is in great demand. Transgenic medicinal plants offer new opportunities to enhance both the quantity and quality of these compounds. Transgenic studies have been conducted on numerous medicinal plant species. *Agrobacterium tumefaciens*, widely applied in transgenic studies, is also used to produce transgenic medicinal plants.

A unique feature of transgenic studies on medicinal plants compared to those on field crops, vegetables, and ornamental plants is the routine use of hairy root technology. Like *A. tumefaciens*, *Agrobacterium rhizogenes* transfers

its transfer DNA (T-DNA) from a plasmid, in this case the root-inducing (Ri) plasmid, to the host genome, inducing the formation of hairy roots (Chilton *et al.*, 1982; Nilsson and Olsson, 1997). *A. rhizogenes* can also harbor a binary vector carrying foreign genes, and the T-DNA of the binary vector can be transferred to the plant genome accompanied by the T-DNA of the Ri plasmid, enabling the production of transgenic hairy roots (Simpson *et al.*, 1986). *A. rhizogenes*-mediated transformation has several desirable features for the production of secondary metabolites. First, hairy root cultures, unlike undifferentiated cell cultures, can usually synthesize the same compounds as the roots of the intact plant. In 1986, three study groups independently demonstrated the production of secondary metabolites by hairy root cultures, including the production of tropane alkaloids by *Atropa belladonna* (Kamada *et al.*, 1986) and *Scopolia japonica* (Mano *et al.*, 1986), and nicotine by *Nicotiana rustica* (Rhodes *et al.*, 1986). Second, the rapid and efficient induction of hairy roots from explant tissues in a wide variety of plant species, including medicinal plants, has been reported. Third, plant regeneration via hairy roots has been described for important medicinal plants such as *Nicotiana tabacum* (for nicotine production), *Panax ginseng* (ginsenoside) (Yang

Table 1 Metabolic engineering of alkaloid and terpenoid biosynthesis in medicinal plants (after 2001)

Plant species	Enhanced metabolite	Introduced gene	Transformation plant/tissue	Transgenic	Reference
Tropane and nicotine alkaloids					
<i>Atropa belladonna</i>	Hyoscyamine, scopolamine	Tropinone reductase I	<i>A. rhizogenes</i>	Hairy root	Richter <i>et al.</i> , 2005

and Choi, 2000), *Papaver somniferum* (morphinan alkaloid) (Park and Facchini, 2000), *Artemisia annua* (artemisinin) (Banerjee *et al.*, 1997), *Scoparia dulcis* (scopadulcic acid) (Yamazaki *et al.*, 1996), and *Ophiorrhiza pumila* (camptothecin) (Watase *et al.*, 2004).

Bajaj (1999) compiled a review of the genetic transformation of more than 25 medicinal plants. Table 1 summarizes recent progress transgenic studies in medicinal plants. In this chapter, recently advanced topics are summarized first, and then transgenic studies on two important medicinal

plants, *Glycyrrhiza* species and *O. pumila*, are reviewed.

2. RECENT PROGRESS IN TRANSGENIC STUDIES ON MEDICINAL PLANTS

2.1 Tropane- and Nicotine Alkaloid-Producing Plants

The members of the family Solanaceae produce a range of biologically active alkaloids, including

nicotine and tropane alkaloids. Tropane alkaloids, such as hyoscyamine and scopolamine, which are mainly found in *Atropa*, *Duboisia*, *Hyoscyamus*, and *Scopolia* species, together with their semi-synthetic derivatives, are useful as parasympatholytics that competitively antagonize acetylcholine (Yamada and Tabata, 1997). The ease of a tissue culture procedure depends on the plant species. The tissue culture of both *A. belladonna* and *Nicotiana* species is straightforward. Because these two plant species produce important alkaloids, tropane and nicotine alkaloids, respectively, various *in vitro* methods for these plants have been developed (Bajaj, 1999). In the early 1990s, the overproduction of hyoscyamine-6 β -hydroxylase (H6H) in *A. belladonna* was found to efficiently convert hyoscyamine to scopolamine in both transgenic plants (Yun *et al.*, 1992) and transgenic hairy roots (Hashimoto *et al.*, 1993). In tobacco, increasing the activity of ornithine decarboxylase in *N. rustica* can result in increased nicotine content (Hamill *et al.*, 1990). The N-methylation of putrescine catalyzed by putrescine N-methyltransferase (PMT) is the first committed step in the biosynthesis of both tropane and nicotine alkaloids. The overexpression of the tobacco PMT cDNA (complementary DNA) in *Nicotiana sylvestris* increased its nicotine content, whereas the suppression of endogenous PMT activity severely decreased the nicotine content (Sato *et al.*, 2001). To effectively control metabolic flow, it is important to regulate the genes that encode the enzymes in a given pathway.

Oksman-Caldentey's group also investigated intensively the metabolic engineering of tropane and nicotine alkaloids. The H6H gene alone or in combination with other genes has been further transferred to different tropane-alkaloid producing plant species. Transgenic root cultures of *Hyoscyamus muticus* with H6H gene were able to produce over 100 times more scopolamine than the control culture (Jouhikainen *et al.*, 1999). While overexpression of only PMT gene in *H. muticus* and *Datura metel* resulted in only slight changes on tropane alkaloid levels (Moyano *et al.*, 2003), when both PMT and H6H genes were simultaneously overexpressed in the hairy roots of *Hyoscyamus niger*, a significantly high scopolamine production was achieved (Zhang *et al.*, 2004).

2.2 Useful Terpenoid-Producing Plants

Terpenoids (isoprenoids) belong to a large chemical family of more than 20 000 compounds that have been isolated from various plants. Plant terpenoids are produced in the cytosol, plastids, and mitochondria. All isoprenoids are biosynthesized from common C5 isoprene units: isopentenyl diphosphate (IPP) and its isomer dimethylallyl diphosphate (DMAPP). Unlike animals, plants synthesize IPP and DMAPP via two pathways, the cytosolic mevalonate (MVA) pathway and the plastidal 2-C-methyl-D-erythritol-4-phosphate (MEP) pathway. Sesquiterpenes, triterpenes, and sterols are biosynthesized via the MVA pathway, whereas monoterpenes, diterpenes, carotenoids, and chlorophyll side chains are biosynthesized via the MEP pathway.

A. annua (Asteraceae) has a long history of use in traditional Chinese medicine. Artemisinin, a sesquiterpene lactone, is a new and highly effective antimalarial drug (Klayman, 1985). Because *A. annua* is currently the only source of artemisinin, extensive chemical and molecular genetic studies focused on sesquiterpenoid biosynthesis in this plant have been performed. Several transformation protocols for *A. annua* using *A. tumefaciens* (Han *et al.*, 2005) and *A. rhizogenes* (Banerjee *et al.*, 1997) have been reported. Farnesyl diphosphate is a general precursor of sesquiterpenoids. When farnesyl diphosphate synthase was overexpressed in *A. annua*, the plants synthesized 30% more artemisinin than nontransgenic *A. annua* (Han *et al.*, 2006a). Recently, two enzymes, amorpho-4,11-diene synthase (ADS), one of the sesquiterpene synthases (Mercke *et al.*, 2000), and CYP71AV1, a P450 monooxygenase that oxidizes amorpho-4,11-diene to artemisinic acid (Ro *et al.*, 2006; Teoh *et al.*, 2006), have been shown to have key roles in artemisinin biosynthesis. A study of transgenic plants overexpressing both ADS and CYP71AV1 would be of interest.

Triterpenes exhibit a wide range of structural diversity and biological activities, and these saponin glycosides are economically important as natural medicines. Squalene synthase (SS) catalyzes the first enzymatic step toward both triterpenoid and sterol biosynthesis (Abe *et al.*, 1993). Increased synthesis of SS in both *P. ginseng* (Lee *et al.*, 2004) and *Eleutherococcus senticosus*

(Seo *et al.*, 2005) enhanced the triterpenoid and sterol levels in transgenic plants of both species. Triterpenoids and sterols are formed by the cyclization of 2,3-oxidosqualene. This cyclization, which is catalyzed by oxidosqualene cyclases (OSCs), is one of the most complicated and fascinating reactions found in nature. Whereas OSCs in vertebrates and fungi only convert 2,3-oxidosqualene into lanosterol, a sterol precursor, OSCs in plants convert 2,3-oxidosqualene into cycloartenol and some other cyclic triterpenes (Suzuki *et al.*, 2006; Suzuki and Muranaka, 2007). Plant triterpenes have diverse structures with more than 100 different carbon skeletons, and plants correspondingly have several genes that encode OSCs. Han *et al.* (2006b) isolated dammarediol synthase (DDS), one of the OSCs of *P. ginseng*. This study demonstrated that the treatment of transgenic *P. ginseng* with DDS RNAi results in the silencing of DDS expression, which leads to reduced ginsenoside production in roots. These results suggest the possibility of changing triterpenoid profiles by manipulating a specific OSC. The following section details tissue culture and transgenic studies of *Glycyrrhiza* plants, important triterpene-saponin producing plants that could be used as practical model plants.

2.3 Glycyrrhiza Species

2.3.1 *In vitro* studies of *Glycyrrhiza* plants

The dried root and subterranean stem (stolon) of some species of *Glycyrrhiza* plants (licorice, Leguminosae; Figure 1) are some of the most important drugs used in oriental traditional medicine as anti-inflammatory, antiallergenic, and antiulcer agents. Licorice is also an important commercial product used as a sweetener and a flavor in many foods, tobacco, and confections. The root and stolon contain several compounds of interest, the most important of which is glycyrrhizin (Figure 2), a triterpene saponin. Licorice can grow in only limited regions, including semi-arid areas of southern Europe and Asia. Recently, however, the exhaustion of natural resources and desertification has occurred in these regions. Most licorice is harvested from wild plants or cultivated under intensive farming. Because the quantity and the quality of these products are

Figure 1 Plants of *Glycyrrhiza uralensis* (In the research field in Division of Tsukuba, Research Center for Medicinal Plant Resources, National Institute of Biomedical Innovation, Japan)

not sufficiently stable for use in drugs, demand for breeding modern licorice cultivars has recently increased. The development of a rapid *in vitro* propagation method is necessary to breed licorice, and research is also needed to obtain large biomass and secondary metabolite (e.g., glycyrrhizin) yields in a *Glycyrrhiza* tissue culture system.

2.3.2 Micropropagation

A few reports on the *in vitro* propagation of *Glycyrrhiza* plants have been published (Table 2). *In vitro* propagation methods using *Glycyrrhiza* nodal stem segments or other explants are summarized in Henry *et al.* (1991). Multiple shoots produced from *Glycyrrhiza glabra* axillary buds excised from growing plants have been reported (Kohjyouma *et al.*, 1995; Figure 3), and Kakutani *et al.*

^(a)Studies before 1990 were summarized by Henry *et al.* (1991)

^(b)MS, Murashige and Skoog (1962); LS, Linsmaier and Skoog (1965); B5, Gamborg *et al.* (1968); NAA, naphthaleneacetic acid; IAA, indole-acetic acid; BA, benzylaminopurine; 2,4-D, 2,4-dichlorophenoxyacetic acid; MeJ, methyl jasmonate

Figure 3 Multiple shoots developed from an axillary bud of *Glycyrrhiza glabra* (a). Regenerated plantlets with adventitious roots (b)

(1999) described the somatic embryogenesis of *Glycyrrhiza echinata* and *Glycyrrhiza squamulosa*.

In vitro stolon cultures of *Glycyrrhiza uralensis* have been established (Figures 4 and 5; Kojoma *et al.*, 2005). The formation of a stolon was induced from a single stem node in Murashige and Skoog (MS) liquid medium supplemented with $0.01 \mu\text{M}$ α -naphthaleneacetic acid (NAA) and grown in darkness. This concentration of NAA and 6% sucrose comprised the best conditions for proliferating the stolon. Adventitious root and shoot regeneration from cultured stolons were easily achieved on MS medium containing $0.01 \mu\text{M}$ NAA and 0.2% Gelrite and culture in light.

2.3.3 Secondary metabolites

Several chemical studies have been conducted on callus and suspension cultures of *Glycyrrhiza* plants (Table 3; the reports published before 1990 are summarized in Henry *et al.*, 1991). Hayashi *et al.* (1988, 1990a, b) reported the biosynthesis of triterpene, betulinic acid, and soyasaponins I and II in *G. glabra* cell suspension cultures, and Aris-Castro *et al.* (1993a, b) described the production of the isoflavonoid formononetin. Chalcones and isoflavones were isolated from callus cultures of *G. uralensis* (Kobayashi *et al.*,

1985), and flavonoid production in cell suspension cultures of *G. echinata* was investigated (Ayabe *et al.*, 1980, 1986; Nakamura *et al.*, 1999).

A few reports have described glycyrrhizin production in cultured tissues (Tamaki *et al.*, 1973, 1975 in, e.g., *G. glabra*, *G. uralensis*, and *G. echinata*; Fujita *et al.*, 1978 in various *Glycyrrhiza* species; Ko *et al.*, 1989 in *G. uralensis*). However, no efforts have been made to produce glycyrrhizin in cultured tissues since that of Ko *et al.* (1989).

2.3.4 Transgenic studies

Although no study has examined the establishment of transgenic *Glycyrrhiza* plantlets, the development of *Glycyrrhiza* hairy root cultures by transformation with *A. rhizogenes* containing Ri plasmids has been reported (Table 3). Many flavonoids have been isolated from *G. glabra* hairy roots by Asada *et al.* (1998, 1999, 2000) and Li *et al.* (2000). Toivonen and Rosenqvist (1995) reported the production of phenolic substances.

Saito *et al.* (1990) showed β -glucuronidase (GUS) reporter gene expression in *G. uralensis*. A hairy root culture was also established by infecting cultured *G. uralensis* stolons (Kojoma *et al.*, 2005). In these hairy root cultures, green fluorescent protein (GFP) reporter gene expression was detectable (Figure 6; Kojoma *et al.*, 2003).

Figure 4 Schematic of the *in vitro* stolon formation and hairy roots induction

2.4 Ophiorrhiza pumila

2.4.1 Camptothecin-producing plants

Camptothecin (CPT) (Figure 7: 1) is one of most important antineoplastic alkaloids of plant origin, and its semi-synthetic water-soluble analogs topotecan (Figure 7: 2) and irinotecan (Figure 7: 3)

are used as clinical antitumor agents throughout the world. The worldwide market of irinotecan/topotecan is currently 1 billion US dollars. In spite of the rapid growth of the market, CPT is still extracted from the seeds of *Camptotheca acuminata* and the bark of *Nothapodytes foetida*.

CPT was first isolated from *C. acuminata* during a screening for antitumor agents by the

Figure 5 *In vitro* cultured stolon from a nodal stem segment of *Glycyrrhiza uralensis* in MS liquid medium with 0.01 μ M NAA

National Cancer Institute in the United States (Wall *et al.*, 1966). CPT has been found in not only *C. acuminata* (Nyssaceae) (Figure 8a) and *N. foetida* (Icacinaeae) (Figure 8b) but also in several other plant species belonging to various plant families, including the Rubiaceae, Apocynaceae, and Gelsemiaceae. The genus *Ophiorrhiza* (Rubiaceae) is widely distributed throughout tropical and temperate Asia, and 150 species belong to this genus. CPT has been detected in four species: *O. pumila* (Figure 8c), *Ophiorrhiza liukuensis* (Figure 8d), *Ophiorrhiza kuroiwa*, and *Ophiorrhiza mungos*.

2.4.2 CPT production by *O. pumila* hairy root cultures

Although Sakato *et al.* (1974) first reported on the establishment of *C. acuminata* cell suspension cultures, however, the levels of CPT production in

these cultures were insufficient. Hairy root cultures induced by *A. rhizogenes* are an attractive method for producing CPT because of their potential for stable, high yields. Saito *et al.* (2001) developed the first feasible CPT production system in *O. pumila* hairy root cultures. In these hairy roots, CPT accumulated at levels similar to those in the roots of the original plants and was excreted into the culture medium in large quantities. These hairy root cultures have been grown in 3-L bioreactors for the production of CPT (Sudo *et al.*, 2002). In addition, *C. acuminata* hairy roots that produce an equal level of CPT have been reported (Lorence *et al.*, 2004), but no studies have reported on hairy root cultures of *N. foetida*, the main species used for the production of CPT in Japan.

2.4.3 *O. pumila* genetic transformation and plant regeneration

For better production of CPT and further genetic engineering, regeneration protocols for transformed plants of the above CPT-producing species are needed. Watase *et al.* (2004) reported a method for plant regeneration from *O. pumila* hairy roots. This group infected sections of *O. pumila* shoot cultures with *A. rhizogenes* strain 15835. The established hairy root cultures were subcultured in fresh B5 (Gamborg *et al.*, 1968) gellan gum-solidified medium once per month and grown under dark conditions. Hairy roots of about 1 month of age spontaneously developed several shoot buds in darkness. The hairy root cultures with shoot buds were exposed to light (Figure 9a), and the shoot buds that turned green were transferred to half-strength MS (Murashige and Skoog, 1962) solid medium containing 1% sucrose for rooting. The regeneration frequency was over 83%: 33 lines from 40 randomly selected hairy roots regenerated. The regenerated plants showed typical features of hairy root-derived plants, including short internodes and malformed leaves (Figure 9b). The transformed plants accumulated CPT in amounts 66–111% of those in wild-type plants. To date, this is the only report describing the generation of transgenic CPT-producing plants.

2.4.4 The future of CPT research

Although the skeleton of CPT belongs to the quinoline alkaloid group, it is synthesized

Table 3 Summary of transgenic studies of *Glycyrrhiza* plants with *Agrobacterium rhizogenes*

Plant species	Strain of <i>Agrobacterium</i>	Vector	Part of infection	Chemical compound	Reference

<i>G. pallidiflora</i>		pRi 15834, pGSGlucI (GUS)	Aseptic young plant	Licoagroside D, etc.	Li <i>et al.</i> , 2002

via strictosidine, a common intermediate of monoterpenoid indole alkaloids (Hutchinson *et al.*, 1979). Some of the genes that encode the key enzymes involved in the biosynthesis of these alkaloids have been identified. The cDNAs encoding strictosidine synthase (STR) and tryptophan decarboxylase (TDC) have been isolated from *Rauvolfia serpentina* (Kutchan *et al.*, 1988), *Catharanthus roseus* (De Luca *et al.*, 1989; McKnight *et al.*, 1990), and *O. pumila* (Yamazaki *et al.*, 2003a). However, the biosynthetic pathway after strictosidine to CPT and the regulatory steps of the biosynthetic pathway are still unclear (Figure 10). Three plausible precursors of CPT, 3(*S*)-pumiloside and 3(*S*)- and 3(*R*)-deoxypumiloside, have been isolated from *O. pumila* (Aimi *et al.*, 1989; Kitajima *et al.*, 1997). A feeding study with *O. pumila* hairy roots revealed that the secologanin moiety of CPT is synthesized via the MEP pathway (Yamazaki *et al.*, 2004). The enzymatic activity of STR and the expression

of the corresponding mRNA were measured in several *O. pumila* tissues, callus, and hairy roots, and compared to the metabolic profiles of those tissues. The patterns of enzymatic activity of STR and the expression of its mRNA were roughly correlated with the accumulation of CPT (Yamazaki *et al.*, 2003b). *O. pumila* will be a suitable species for metabolic studies of CPT-producing plants because it is straightforward to obtain transformed tissue and genetically transformed plants of this species.

3. FUTURE PROSPECTS OF TRANSGENIC MEDICINAL PLANT DEVELOPMENT

In this chapter, recent advances in transgenic studies on medicinal plants were summarized, and detailed studies on the tissue culture and transgenic plant generation of two important medicinal plants with potential use as practical models

Figure 6 Hairy roots from the cultured stolon of *Glycyrrhiza uralensis* infected with *Agrobacterium rhizogenes*. (a) Light (b) and fluorescent micrographs (c) of GFP-expressing hairy roots

were described. Although routine transgenic plant generation protocols are available for some medicinal plants, efforts are continuing to establish efficient protocols for *Glycyrrhiza* species and *O. pumila*. Research on each step in a tissue culture

protocol is still important for success in this field. Recently, a high-throughput system for activation tagging in transformed hairy roots was established (Seki *et al.*, 2005). This approach will identify genes involved in root-specific secondary metabolites or

Figure 10 The predicted biosynthesis pathway of camptothecin in *O. pumila*. The enzymes are: TDC, tryptophan decarboxylase; STR, strictosidine synthase

secretion in various medicinal plants. Although a large amount of genome and gene expression information is available for several plant species, such information is still limited for many medicinal plants. As described here, transgenic medicinal plants offer new opportunities to enhance both the quantity and quality of useful compounds. For this purpose, it is important to determine the general concepts and methodology to apply this abundant information to medicinal plants of interest.

1. INTRODUCTION

Substantial economic returns are generated by the sales of cut flowers, potted, and bare-rooted ornamental plants. The revenue generated for cut flowers alone exceeds US\$27 billion per annum, representing about one-third of the total market income (Chandler, 2003; Tanaka *et al.*, 2005). Consumer demand for greater novelty, particularly in terms of flower form and color, drives the search for new genetic material. Conventional breeding, through sexual hybridization and selection, has maintained the generation of this genetic novelty and it is unlikely that plant breeders will lose their momentum in this area. More recently, biotechnological approaches have been developed that are an important adjunct to conventional approaches. Such procedures, based on the robust culture of totipotent cells and tissues, include somatic hybridization through protoplast fusion and transformation exploiting recombinant-DNA technology. Exposure of genetic variation through the culture of somatic cells may be superimposed on these gene transfer procedures. Whilst there has been less input of effort and finance into the application of biotechnology to ornamental plants compared to the massive investment into crops for human nutrition and animal feed, it is certain that biotechnological procedures also have considerable potential for improving ornamental plants. Such approaches will be exploited increasingly in the immediate future.

Several excellent reviews have been published recently that summarize the extensive literature relating to plant cell culture and transformation of ornamental plants, to which the reader is referred in the present text. For example, Li and Pei (2006a, b) have edited two volumes devoted to aspects of transformation technologies as applied to ornamental plants, while Teixeira da Silva (2006a) has edited an excellent series of four volumes devoted to all aspects of the biotechnology of ornamental plants. Additionally, the journal “*Global Plant Letters*”, also edited by Teixeira da Silva (2006b) and initiated in 2006 to coincide with the formation of the International Society for Floricultural and Ornamental Plants (ISFOP), is intended to raise the profile of ornamental plants and related research. Consequently, the present article directs the reader to some of the most recent and relevant publications.

2. DEVELOPMENT OF TRANSGENIC ORNAMENTALS

2.1 Targets for Genetic Manipulation of Ornamental Plants

Harriman *et al.* (2006) discussed the ways that the horticultural industry may benefit from current state-of-the-art biotechnological procedures. Micropropagation has facilitated the mass

propagation of elite plants, with more sophisticated recombinant-DNA procedures being superimposed on this technology in recent years. The targets for transformation of ornamental plants by somatic cell techniques parallel, in many ways, those of conventional breeding. Additionally, the targets for ornamentals are similar to those for other crops with the need to improve tolerance to abiotic stresses such as drought, cold, heat, salinity, and light, and to increase disease resistance. Additional traits for modification that are specific to ornamentals, include flower color, scent, longevity following cutting and alteration of plant morphology. Modification of physiology through endogenous growth regulators has the potential to generate changes beneficial to the horticultural industry.

Molecular fingerprinting procedures have become important tools in clarifying the parentage and genetic relationships of existing species and cultivars, and in identifying plants most suitable as donors for introgressing horticulturally important traits into existing species and cultivars through both sexual hybridization and cell culture-based technologies (Handa *et al.*, 2006). For example, Aros *et al.* (2006) used random amplified polymorphic DNA (RAPD) analysis to discriminate nine wild *Alstroemeria* accessions and 10 commercial varieties, while Chen *et al.* (2006a) employed amplified fragment length polymorphism (AFLP) markers to detect genetic differences in 19 cultivars of tissue culture-derived somaclonal variants of *Syngonium podophyllum*. Similarly, Chen *et al.* (2006c) used sequence tag site (STS) markers developed through AFLP fingerprinting to distinguish new cultivars of orchids of the genus *Oncidium*. This technology has application in distinguishing existing and new cultivars, especially in relation to Plant Breeders' Rights. Scariot *et al.* (2006) exploited polymorphic sequence-tagged microsatellite sites (STMs) to characterize 65 accessions of old garden roses. Importantly, the seven major clusters developed from these analyses were consistent with earlier grouping of the roses into botanical sections and horticultural groups. RAPD analyses based on morphology, physiological and ecological characteristics were used to substantiate the classification of oriental *Cymbidium* species (Choi *et al.*, 2006).

2.2 Somatic Cell Techniques for Genetic Manipulation of Ornamentals

2.2.1 Micropropagation, organogenesis, and somatic embryogenesis

Robust culture procedures that enable cells and tissues to express their totipotency through organogenesis and/or somatic embryogenesis are fundamental to the generation of novel plants by somatic cell approaches. Rout *et al.* (2006) reviewed the literature until October 2005 and concluded that approximately 156 ornamental genera are micropropagated through the culture of meristems, axillary buds, and shoot tips. These authors provided a comprehensive table listing the micropropagation of major ornamental species. An added advantage of meristem culture is that it is a procedure for virus elimination. Other explants used routinely for ornamental species include those from tubers, leaf laminae, and petioles. Rout *et al.* (2006) also summarized the effects of physical factors, including illumination and semisolid and liquid culture media, on shoot regeneration by organogenesis and/or somatic embryogenesis, with a summary of the major ornamentals in which somatic embryogenesis is the primary pathway of plant regeneration. Detailed case studies were discussed for *Ficus* and *Yucca* spp., African violet, begonia, chrysanthemum, cyclamen, and rose. Other topics of this excellent review included aspects of germplasm conservation, *in vitro* mutagenesis, cryopreservation, and somaclonal variation. Other authors have focused attention upon high-value crops, particularly chrysanthemum, since it is one of the most important global cut flowers and pot plants. Thus, Teixeira da Silva (2003) presented an outstanding and comprehensive review of the advances achieved in the culture, cryopreservation, postharvest technology, synthetic seed production, genetics, and transformation approaches of ornamental plants.

Hazarika (2006) discussed some of the morphological and physiological disorders associated with *in vitro*-grown plants and the influence of these abnormalities on the acclimation of regenerated plants to *ex vitro* conditions. More recent papers on the tissue culture of ornamentals emphasize the diversity of target species. For example,

investigations have focused on plant regeneration by somatic embryogenesis in *Catharanthus roseus* (Junaid *et al.*, 2006), *Lilium* × *formolongi* (Ho *et al.*, 2006), *Oncidium* (Jheng *et al.*, 2006), *Euphorbia pulcherrima* (Castellanos *et al.*, 2006), and *Syngonium podophyllum* (Zhang *et al.*, 2006). Polyamines and L-ornithine influence the development of embryogenic tissues in *Cryptomeria japonica* (Nakagawa *et al.*, 2006). Other reports describing plant regeneration by organogenesis, relate to the genera *Acacia* (Yang *et al.*, 2006), *Kniphofia* (Dalia *et al.*, 2006), *Bambusa* (Kapoor and Rao, 2006), the effects of growth regulators, particularly thidiazuron (TDZ) on shoot regeneration in *Kalanchoë* (Sanikhani *et al.*, 2006), and 6-benzylaminopurine in stimulating organogenesis in *Eucalyptus erythronema*, *E. stricklandii*, and their interspecific hybrids (Glocke *et al.*, 2006a, b). Chen *et al.* (2006b) micropropagated *Lychnis senno*, a rare plant with potential as an ornamental, while Ma and Wu (2006) regenerated shoots from cotyledons of *Ochna integerrima*, a medicinal and ornamental plant from southeastern Asia. Dewir *et al.* (2006) scaled up the micropropagation of *Spathiphyllum* using an airlift bioreactor, while Teixeira da Silva *et al.* (2006a) developed a photoautotrophic micropropagation system for this ornamental and novel culture vessels for shoot multiplication under carbon dioxide enrichment (3000 ppm) at low photon flux density. *Lilium* has also been targeted in liquid medium in bioreactors (Thakur *et al.*, 2006). Wang and Bhalla (2006) initiated cell suspensions from leaf and root callus cultures of the Australian ornamental plant, *Scaevola aemula*.

Micropropagation of orchids has received considerable attention because of the commercial requirement for large numbers of cut flowers and potted plants. Additionally, multiplication of shoots in culture is important for those orchids that are endangered. Indeed, the technique has been applied to several genera, including *Cymbidium* and *Phalaenopsis* (Chen and Chang, 2006), *Cypripedium* (Yan *et al.*, 2006), *Dendrobium* hybrids (Martin and Madassey, 2006), *Laelia* (Santos-Hernandez *et al.*, 2005), and intergeneric sexual hybrids between *Ascocentrum* and *Vanda* (Kishor *et al.*, 2006). A robust micropropagation protocol was developed and reported for *Cymbidium* (Teixeira da Silva *et al.*, 2006b). Other

ornamental plants that have been targeted include bromeliads, such as the Brazilian *Vriesea reitzii*, with 90% survival *ex vitro* of the regenerated plants (Alves *et al.*, 2006). Similar success has been achieved with *Tillandsia eizii*, a large colorful plant with persistent flowers up to 1 m in length but which, like *V. reitzii*, is endangered through collecting in the wild (Pickens *et al.*, 2006). Woody plants, such as Japanese photinia (*Photinia glabra*) have received attention (Li *et al.*, 2006a), as have succulents such as *Notocactus magnificus* (de Medeiros *et al.*, 2006). Hatzilazarou *et al.* (2006) correlated the rooting of micropropagated shoots of *Gardenia jasminoides* with peroxidase activity. Literature relating to other recent micropropagation reports and tissue culture-based procedures for ornamental plants have been summarized by Teixeira da Silva (2006c), together with short synopses of the scientific relevance of the contents of the publications. Jain *et al.* (2006) discussed the commercial application of *in vitro* techniques, especially of micropropagation, to satisfy the demand for ornamental potted plants such as *Begonia*, *Cyclamen*, *Ficus*, *Philodendron*, *Rhododendron*, *Saintpaulia*, and *Spathiphyllum*.

2.2.2 Protoplast-based technologies

Isolated protoplasts are essential for gene transfer by somatic hybridization, cybridization, and some aspects of transformation. Details of parameters such as source material, plant genotype, and aspects of protoplast isolation have been reviewed (Davey *et al.*, 2005). The composition of culture media, growth regulators, and gelling agents has also been considered. Innovative approaches to protoplast culture include electrostimulation and the influence of nonionic surfactants, antibiotics, and polyamines on growth, with the use of perfluorochemicals and haemoglobin to modify the gaseous environment within culture vessels. Winkelmann *et al.* (2006) developed a protocol for isolating protoplasts from cell suspensions of *Cyclamen persicum*, with subsequent culture of the protoplasts in alginate films. Protoplast-derived plants of four genotypes were transferred to compost. Komai *et al.* (2006) reported that sustained mitotic division of protoplasts of *Lilium japonicum* necessitated the use of nurse cell culture.

2.3 Genetic Manipulation of Ornamental Plants through Protoplast-to-Plant Technology

2.3.1 Somatic hybridization to combine genetic information from genera and species

Protoplast fusion circumvents pre- and postzygotic sexual incompatibility barriers, permitting nuclear and/or cytoplasmic genomes to be combined from different donors to generate somatic hybrid and cybrid plants. The fusion of protoplasts presents few difficulties. Treatments of isolated protoplasts with polyethylene glycol (PEG), electrofusion, or a combination of these techniques, are the procedures generally employed to fuse isolated protoplasts. The cells and tissues resulting from the heterokaryons generated by fusion may regenerate to plants with balanced or asymmetric nuclear genomes (Davey *et al.*, 2000). Usually, chloroplasts segregate or, more rarely, remain as a mixed population in heterokaryon-derived cells and regenerated plants. Frequently, the DNAs of mitochondria recombine; elimination of the nuclear genome of one parent may result in the production of cytoplasmic hybrids, with transfer of cytoplasmically encoded traits, such as mitochondrially encoded cytoplasmic male sterility (CMS). Liu *et al.* (2005) discussed the relevance of somatic hybridization to the genetic improvement of cultivated plants, and emphasized the importance of both related and distant species as a pool of desirable genes for introgression into crop plants.

The selection of hybrid/cybid cells prior to plant regeneration remains the most difficult aspect of somatic hybridization. Some selection procedures are complex, being based on mutant and transformed cells, or metabolic inhibitors. In contrast, procedures exploiting hybrid cell vigor (heterosis) are simple, and are based on long-established principles in conventional plant breeding. Davey *et al.* (2000, 2004) reviewed the procedures involved in somatic hybridization and discussed some of the agronomically useful traits that have been introgressed into the major crop plants, especially in nonornamental genera, such as *Citrus*, *Brassica*, and *Solanum* (Davey *et al.*, 2005).

Although limited in extent, success has been reported in fusing protoplasts and in generating somatic hybrids of ornamental species. In studies of the viability of fusion products between mesophyll protoplasts of pansy (*Viola tricolor*) and protoplasts from petiole-derived callus of the wild viola, *V. patrinii*, Kwon *et al.* (1992) examined by electron microscopy the products generated by electrofusion. Heterokaryons and homokaryons were observed in the preparations. Mastuti *et al.* (1997) studied the electrofusion of protoplasts isolated from cell suspensions of *Celosia cristata*, a C3 species, with cotyledon protoplasts of *Amaranthus tricolor*, a C4 species. Fourteen compact protoplast-derived tissues were produced, with acid phosphatase analysis confirming their hybridity. However, plant regeneration from these tissues was not reported. Treatment with PEG was used to fuse leaf protoplasts of *Dianthus chinensis* with those of *D. barbatus* (Nakano and Mii, 1993). Unlike the situation in *Viola*, the protoplasts of the two species of *Dianthus* were morphologically identical. Consequently, it was not possible to distinguish heterokaryons from homokaryons or unfused protoplasts. The selection of potential somatic hybrid tissues was based on heterosis, with the most vigorously growing protoplast-derived tissues being selected manually. Shoots regenerated from one of these tissues were analyzed and flower color, chromosome complement, and esterase pattern showed that one plant was an interspecific somatic hybrid. Subsequently, the hybridity of this individual was confirmed by nuclear ribosomal DNA analysis.

VazquezTello *et al.* (1996b) attempted to transfer cold tolerance from *Lavatera thuringiaca* into *Hibiscus rosa-sinensis*, but plants were not regenerated in this intergeneric combination. In a later report, the same research group discussed the potential application of irradiation in asymmetric protoplast fusion for gene transfer (VazquezTello *et al.*, 1996a). Fertile somatic hybrid plants were generated between the oriental hybrid lily cultivars Acapulco and Shirotae and *Lilium* \times *formolongi* cv. Hikuchō (Horita *et al.*, 2003). However, electrofusion-treated protoplasts divided only in the presence of nurse cells of the cultivar Hikuchō. Molecular analyses, using cleaved amplified polymorphic sequence markers and flow cytometry, confirmed the somatic hybrid

nature of the regenerated plants. Asymmetric and symmetric somatic hybrids between cultivated sunflower (*Helianthus annuus*) and the wild species, *H. maximiliani*, were characterized using RAPD markers (Binsfeld *et al.*, 2001; Binsfeld and Schnabl, 2002). Microprotoplasts from the perennial *Helianthus* species were also fused, using PEG, with protoplasts of the annual species, *H. annuus* (Binsfeld *et al.*, 2000). Both types of hybrids showed recombination to different extents of the two parental nuclear genomes, making some of these plants exploitable for inclusion in conventional breeding programs. These studies extended earlier investigations involving the fusion of protoplasts of *H. annuus* with those of *H. maximiliani*, *H. giganteus*, and *H. nuttallii*, in which fertile hybrids were recovered (Henn *et al.*, 1998). The asymmetric and symmetric fertile somatic hybrids in *Helianthus* exhibited a range of variability (Binsfeld *et al.*, 2003). These authors reported that such hybrids were backcrossed to sunflower prior to assessments of their disease resistance and agronomic performance.

Whilst the genus *Helianthus* is primarily of agronomic importance because of its seed and oil production, interest in "sunflowers" as ornamental plants has gained considerable momentum in recent years, emphasizing the relevance of these studies to create novelty in terms of floral form, pigmentation, and plant stature. The genus *Mentha* is grown in gardens not only for its culinary and medicinal uses, but also as a genus of ornamental value, particularly as a sensory plant. Sato *et al.* (1996) fused protoplasts of peppermint (*M. piperita* cv. Blackmint) with those of gingermint (*M. gentilis* cv. *variegata*) to generate somatic hybrids that synthesized the major volatile oil components menthone, menthol, and linalol, the last two being from peppermint and gingermint, respectively. Subsequently, Krasnyanski *et al.* (1998) fused protoplasts of peppermint (*M. piperita* cv. Black Mitcham) with those of spearmint (*M. spicata* cv. Nature Spearmint) in an attempt to combine the oil quality of spearmint with the disease resistance of peppermint. Modification of secondary product biosynthesis was one of the primary objectives of studies involving the fusion of protoplasts of tansy (*Tanacetum vulgare*) with those of pyrethrum

(*T. cinerariifolium*), to improve the oil content and composition of tansy in order to stimulate the production of environmentally benign pesticides, the pyrethrins (Keskitalo *et al.*, 1999). As already discussed for mint, it will be interesting to see whether or not plants of *Tanacetum* modified genetically by protoplast fusion, will become ornamentals in their own right.

Wang and Binding (1993) characterized somatic hybrids and cybrids between the ornamental plants, *Senecio fuchsia*, and ragwort, *S. jacobaea*, through investigations of chromosome complements, isozyme profiles, and DNA RFLPs (restriction fragment length polymorphisms). Nine plants had the amphidiploid chromosome number of 80; three hybrids had reduced chromosome complements of 60–76, indicating karyotypic instability. Plastomes originated from one or both parents, but chondriomes were from either parent. Eight plants were putative cybrids in which only the mitochondrial DNA of *S. jacobaea* was detected in seven of these plants, with mitochondrial DNA fragments of both parents in the remaining cybrid plants. Three cybrids had the nucleus and plastids of *S. fuchsia*, with mitochondrial DNA of *S. jacobaea*. In other detailed analyses of somatic hybrid plants, Barbosa and Vieira (1997) focused their attention on microsporocytes of somatic hybrids between *Passiflora edulis* f. *flavicarpa* and *P. amethystina*. These workers reported univalents, bivalents and quadrivalents, laggard chromosomes and anaphase bridges. Pollen viability and multivalent pairing in four somatic hybrid plants that were analyzed indicated this material may be exploited in the genetic improvement of yellow passion fruit, following the introgression of genes for resistance to pests and diseases. Whilst *P. edulis* is cultivated commercially, mainly as a source of fruit for the extraction of juice, passion flowers, in general, are cultivated extensively as ornamentals because of the beauty of their flowers.

Nicotiana species have become popular as ornamental plants, with genetic manipulation of this genus being important in relation to floral morphology, plant stature, and disease resistance. Ilcheva *et al.* (2000) documented the morphology and cytology of somatic hybrids between *N. tabacum* and *N. megalosiphon*. Both parents were transgenic, enabling the hybrids to be selected on

the basis of their dual resistance to bialaphos and kanamycin. There was no preferential loss of one of the parental genomes in such hybrids. Subsequently, Farbos *et al.* (2001) studied an alloplasmic male-sterile tobacco plant generated by protoplast fusion that consisted of the nuclear genome of *N. tabacum* and the cytoplasm of *N. repanda*. Flowers were morphologically abnormal and developed short, poorly pigmented petals and abnormal sterile stamens that were often fused with the carpel wall. Such abnormalities were attributed to reduced cell division and the size of floral meristems. Defects in cell proliferation were correlated with morphologically modified mitochondria. The same parental species of tobacco were also studied by Sun *et al.* (2005), the selection procedure used to generate the cybrid plants involving inactivation of mesophyll protoplasts of *N. tabacum* var. K326 by rhodamine-6G, before PEG fusion with wild-type protoplasts of *N. repanda*. Thirty-one plants regenerated following fusion treatment resembled the *N. tabacum* parent, apart from their floral morphology and male sterility, the latter confirming the observations of Farbos *et al.* (2001). Cybrid plants had the nuclei of *N. tabacum* and mitochondria from *N. repanda*, in agreement with the earlier report. Backcrossing to *N. tabacum* revealed a strict maternal inheritance of the male-sterile phenotype. Sun *et al.* (2005) emphasized that this methodology is effective for introducing CMS through mitochondrial transfer from wild species, and that this source of CMS is of considerable value in breeding programs.

Other *Nicotiana* species have been used to generate cybrid plants, as in the case of protoplasts of *N. tabacum* with those of *N. suaveolens* (Fitter *et al.*, 2005). Molecular analysis confirmed these cybrids contained mitochondria with both parental DNA sequences, although not all of the parental mitochondrial DNA was present. As earlier, the cybrid plants developed morphologically abnormal flowers, these being similar to the flowers of *N. tabacum*, but with a split corolla and the stamens replaced by a whorl of carpel-like structures. The authors emphasized that such cybrids will facilitate analysis of the role of mitochondrial DNA sequences in floral organ identity. Such information may be applicable to ornamental plants in genera other than *Nicotiana*.

Cybrids have also been generated by fusing protoplasts of tobacco with protoplasts of other members of the Solanaceae, as in *N. tabacum* with *Petunia hybrida* (Dragoeva *et al.*, 1998). Regenerated plants were phenotypically similar to tobacco, were male and female sterile and possessed the nuclear genome of *N. tabacum*, the chloroplasts from *P. hybrida* and recombinant mitochondrial DNA. Zubko *et al.* (2003) investigated the morphology of CMS cybrids possessing the *N. tabacum* nuclear genome, the plastome from *Hyoscyamus niger*, and recombinant mitochondria. Such studies followed earlier work on cybrids of the same genera and those of *N. tabacum* with *Scopolia carniolica* (Zubko *et al.*, 1996). Backcrossing of cybrids with tobacco generated plants with floral modifications, including the conversion of stamens to filamentous structures, modification of petals, and a reduction in most floral organs. Such results indicated that cytoplasm transfer by protoplast fusion, with subsequent conventional backcrossing, generated novel nuclear-cytoplasmic combinations that could be exploitable, in a longer term, in generating useful floral novelty. Undoubtedly, protoplast fusion has resulted in considerable modification of floral morphology in tobacco. Whilst some alterations are detrimental, several are novel and exploitable in achieving long-term breeding objectives. Knowledge accrued from these investigations relating to the genetic control of flower characteristics, should be applicable to future breeding programs not only in tobacco, but also in other ornamental plants.

Most effort has been focused on somatic hybridization in dicotyledons, but progress has been reported in the somatic hybridization of monocotyledonous ornamentals of the genus *Iris*, permitting hybridization that cannot be achieved by conventional breeding. Thus, Shimizu *et al.* (1999) electrofused protoplasts of *I. ensata* with those of *I. germanica*. The selection of symmetric hybrid tissues was based on the growth of protoplasts in culture; selection of asymmetric hybrids employed iodoacetamide inactivation of metabolism. RAPD analysis confirmed the hybrid nature of regenerated plants. It is likely that the genus *Iris* will continue to be targeted in future somatic hybridization programs.

2.3.2 Genetic modification of ornamental plants by DNA uptake into isolated protoplasts

Isolated protoplasts can be induced to take up DNA by chemical and/or physical procedures. These procedures have been important in transforming plants that are not amenable to other methods of gene delivery, particularly *Agrobacterium*-mediated transformation (Rakoczy-Trojanowska, 2002). Both supercoiled and linearized plasmids have been used to transform isolated protoplasts. Treatment of protoplast-plasmid mixtures with PEG and/or electroporation is normally employed to induce DNA uptake into protoplasts, but only about one in every 10 000 protoplasts develops into stably transformed tissues. This emphasizes the necessity for reproducible protoplast-to-plant systems, combined with efficient procedures to select transformed cells and tissues. Protoplasts may be co-transformed with more than one gene carried on the same or separate plasmids. Several parameters influence protoplast transformation, including the plant genotype and the stage of the cell cycle of the recipient protoplasts. Heat shock and irradiation of recipient protoplasts both enhance the transformation frequency (Davey *et al.*, 2000, 2005).

There are limited examples, with no recent reports, of the transformation of protoplasts from ornamental species. Ling and Binding (1997) generated transgenic plants of *Linum usitatissimum* (flax) and the ornamental rockery perennial, *L. suffruticosum* ssp. *salsoloides*, following PEG-mediated uptake of DNA carrying the hygromycin phosphotransferase (*hpt*) gene for hygromycin resistance. Direct DNA uptake was compared with *Agrobacterium*-mediated transformation of protoplast-derived cells, and the advantages of these procedures discussed in relation to previously reported *Agrobacterium* transformation of seedling hypocotyls. As discussed earlier, mint and tobacco are considered as ornamentals in this review. Peppermint (*M. piperita* cv. Black Mitcham) has received attention in terms of gene transfer through both somatic hybridization and transformation. For example, protoplasts from stems were transformed with a binary vector carrying the neomycin phosphotransferase (*nptII*) and β -glucuronidase (*gus*) genes to establish the DNA delivery system. Later, the *gus* gene was

replaced with a limonene synthase gene and transformed plants analyzed for their oil profiles (Krasnyanski *et al.*, 1999). The retention of tissue specificity at the protoplast level is important, because it permits gene constructs to be evaluated in both homologous and heterologous systems. Thus, Martens *et al.* (2002) used protoplasts of tobacco to investigate heterologous expression of dihydroflavonol 4-reductases (DFRs) from various plants, particularly those from sexual hybrids of the ornamental genus *Gerbera*. DFRs catalyze the stereospecific reduction of dihydroflavonols to their respective 3,4-diols (leucoanthocyanidins). Synthesis of functional DFR protein was obtained in protoplasts of *N. tabacum*. Such a protoplast-based approach will be useful for investigating less-understood reactions downstream of DFR in the biosynthesis of anthocyanin, catechin, and proanthocyanidin.

2.4 Genetic Modification of Ornamental Plants by *Agrobacterium*-Mediated Gene Delivery and Particle Bombardment

2.4.1 General background

Details of the molecular biology of *Agrobacterium*-mediated gene delivery to plants is presented in excellent reviews by Newell (2000), Gelvin (2003), Sharma *et al.* (2005), Lacroix *et al.* (2006), and Tzifira and Citovsky (2006). Rakoczy-Trojanowska (2002) has discussed other procedures not based on *Agrobacterium* for delivering DNA to plants, while Altpeter *et al.* (2005) have published a critique of particle bombardment (Biolistics, gene gunning) for DNA delivery. In summarizing the literature, Brand (2006) presented the basic procedures of gene delivery to plants and concluded that more than 40 ornamental genera have been transformed, with *Agrobacterium*-mediated gene delivery being the procedure generally adopted. The cauliflower mosaic virus (CaMV) 35S promoter and the β -glucuronidase (*uidA*, *gus*) genes have featured in many of the reports, particularly in the development of transformation systems. Leaf explants and stem portions have been targeted in most cases, generally with expression of the *nptII* gene and the antibiotic kanamycin in the culture

medium as the system to select transformed cells, tissues, and regenerated shoots.

2.4.2 Expression of genes from the transfer-DNA of *Agrobacterium rhizogenes* and *Agrobacterium tumefaciens* in ornamental plants: modification of plant stature

Plant stature is an important characteristic of ornamental plants. Dwarf plants may be more attractive as container-grown specimens, while longer stems may be an important trait for introduction into cut flowers. As Duan *et al.* (2006) indicated, large quantities of synthetic growth regulators with auxin, cytokinin, and abscisic acid (ABA) activities are used in the horticultural industry to control plant height. Of the genes that naturally elicit a transformation response in plants, the *rol* genes from the transfer-DNA (T-DNA) of *A. rhizogenes* have received considerable attention in modifying the characteristics of ornamentals. Casanova *et al.* (2005) reviewed the literature and discussed the general effects of specific *rol* genes from the T-DNA of *A. rhizogenes*, on plant growth, including *rolA* + *B* + *C*, *rolA* + *B*, and *rolB* or *rolC*, with the latter being under the control of its own promoter, or the CaMV 35S promoter. Of the *rolA*, *B*, *C*, and *D* genes, *rolC* has been investigated most extensively, plants expressing *rolC* showing a range of phenotypes with the most dramatic changes induced by plants expressing *rolC* under the 35S promoter. Generally, *rolC* leads to dwarfism and increased lateral branching giving a compact, bushy phenotype. Smith *et al.* (2006) also discussed the use of the *rolC* gene in dwarfing ornamental plants. *RolC*-transformed plants of *Osteospermum* flowered earlier with more flowers per plant, although the head diameter of the flowers was reduced. *RolC*-transformed carnation plants developed more extensive root systems with an increase in the number of shoots compared to their wild-type counterparts (Zuker *et al.*, 2001). Importantly, the same gene reduced the time to flowering in *Pelargonium* (Boase *et al.*, 2004). *RolD* also promoted flowering in tobacco. However, the transformation response often depends upon the target plant, since flowers, for example, may be reduced or increased in size. The severity of the *rolC* phenotype was related to *rolC* mRNA

(messenger-RNA) (Gardner *et al.*, 2006). Cheng *et al.* (2006) discussed the application of wild-type strains of *A. rhizogenes* and isolated *rol* genes, particularly *rol A* + *B* + *C* and *rolB*, to stimulate adventitious root development in hardwood cuttings. As indicated by these authors, the effects of *rolD* expression in ornamental plants are less well understood. Sterility may not be a problem in ornamental plants transformed by *rol* genes or, indeed, by other genes, since many ornamentals, such as carnation, are propagated mainly vegetatively.

Genes from the T-DNA of the Ti (tumor-inducing) plasmid of *A. tumefaciens* have been expressed in ornamental plants. Khodakovskaya *et al.* (2006) demonstrated the use of the isopentenyl transferase (*ipt*) gene to manipulate cytokinin biosynthesis in transgenic plants. For example, *ipt* under the control of a fragment of the 1-aminocyclopropane-1-carboxylic acid oxidase gene from tobacco increased flower bud initiation, altered branching and prolonged retention of leaf chlorophyll in *N. tabacum*. The auxin synthase genes, *iaaM* and *iaaH*, also from the T-DNA of the Ti plasmid of *A. tumefaciens*, have been used to induce root formation in transgenic plants. *IaaM* encodes tryptophan monooxygenase that converts tryptophan to indoleacetamide (IAM); *iaaH* encodes indoleacetamide hydrolase, converting IAM to indoleacetic acid (IAA). The *iaaM* gene increased the number of flowers per inflorescence and the number of inflorescences per plant in some members of the Rosaceae. Down-regulation of auxin concentration has been exploited to confer dwarfing with increased flowering, as in chrysanthemum (McAvoy *et al.*, 2003) transformed with the *iaaL* gene that encodes IAA-lysine synthase. Modification of plant stature by reducing growth is also possible by down-regulation of cytokinin synthesis through cytokinin oxidase/dehydrogenase genes, with expression of such a gene cloned from *Dendrobium* reducing shoot growth. Antisense expression of the gene also stimulated the development of short, lateral adventitious roots (Yang *et al.*, 2003).

Since gibberellins (GAs) control several aspects of plant development (Hedden, 2003), it is not surprising that regulation of GA metabolism can be exploited to control plant characteristics, including stature. However, the effect of such genes depends upon their origin. For example,

Mino *et al.* (2006) indicated a GA20 oxidase gene from pumpkin seeds produces physiologically inactive GAs as it catalyzes the conversion of GA19 and GA24 to GA17 and GA25, respectively, resulting in reduced stem growth in transgenic plants. In contrast, overexpression of GA20ox from *Arabidopsis thaliana* in transgenic plants of the same species, which did not divert active GA to GA17 and GA25, increased GA synthesis with a GA-overproduction phenotype. GA2 and 3 oxidase genes have been used to generate dwarf phenotypes in *A. thaliana*, hybrid poplar, and rice. Currently, there is little information relating to the expression of GA biosynthetic genes in ornamentals, but it is clear that the resulting phenotype may depend upon the target species.

2.4.3 Modification of floral morphology, pigmentation, scent, and longevity

Modification of flowering by increasing the number of flowers, reducing the period to flowering and creating novelty, are prime targets for conventional plant breeding and can also be addressed through somatic hybridization and transformation. Vainstein (2002) emphasized that the limited knowledge of the genetics of many ornamental plants restricts their breeding. Several genes are involved in flower induction and development and the changes that they elicit have been discussed by Giovannini *et al.* (2002) and Giovannini (2006). Floral morphology is important in ornamental plants, with Feng *et al.* (2006) investigating the molecular mechanisms underlying the development of zygomorphic flowers in angiosperms using *Lotus japonicus* as a model. Although this plant is not an ornamental, the information from these investigations may be of relevance, in a longer term, to ornamental plants. Tsai *et al.* (2006) studied gene expression in native diploid orchids of the genus *Phalaenopsis* from Taiwan to increase understanding of floral form in the orchidaceae. The time of flowering can be controlled. For example, Boss *et al.* (2006) delayed flowering by overexpressing a *TERMINAL Flower 1* homolog from grapevine (*VvTFL1*) in tobacco. Such information may be crucial in future gene introduction to modify floral development in orchids and other ornamental plants.

Modification of floral pigmentation is, undoubtedly, one of the most dramatic effects of genetic manipulation. Tanaka *et al.* (2005) discussed the range of floral colors generated in carnation following introduction of flavonoid genes from petunia, and the introduction of delphinidin genes for blue pigmentation from pansy to rose. Other reports have focused on alteration of the carotenoids of marigolds, as the latter are a source of natural pigments for the poultry feed industry to enhance the color of egg yolks. Harriman *et al.* (2006) provided the references relevant to these investigations. Modification of flower color demands knowledge of the complex biochemical pathways associated with pigmentation. Flavonoids and carotenoids are major plant pigments, but the final flower color may be influenced by betalains, chlorophylls, and indigo-related compounds (Rosati and Simoneau, 2006). These latter authors provided examples of target plants, gene constructs, and the effect of specific transgenes on flower pigmentation. Modification of flavonoids has involved down-regulation by gene silencing through expression of antisense RNA, homologous sense RNA (co-suppression), and RNA interference (RNAi). Overexpression of flavonoid genes to increase synthesis of existing pigments is also feasible and has been exploited to modify petal color, although the effects of vacuolar pH and the effects of other pigments often influence final petal pigmentation (Forkmann and Martens, 2001).

Aurone flavonoids give plants, such as those of the genera *Antirrhinum* and *Dahlia*, their bright yellow colors. Changes from white to yellow, orange, and pink colors have been induced in petunia. In modifying flower pigmentation, Ono *et al.* (2006) co-expressed chalcone 4'-O-glucosyltransferase and aureusidin synthase genes in *Torenia hybrida* to give this plant yellow petals. They concluded that chalcones are 4'-O-glucosylated in the cytoplasm, their 4'-O-glucosides being transported to the vacuole where the glucosides are converted enzymatically to aurone 6-O-glucosides. The authors emphasized that the metabolic pathway is unique and opens the way to engineer yellow flowers for major ornamental plants that currently lack this color.

Pigment distribution determines color patterns of flowers, with Morita *et al.* (2006) using

Ipomoea nil and *Dianthus caryophyllus* to investigate transcriptional regulation for anthocyanin biosynthesis. Koseki *et al.* (2005) reported that corolla sectoring in the petunia cv. Red Star was attributed to post-transcriptional gene silencing by double-stranded RNA (dsRNA). Flavonoid 3' hydroxylase (*GtF'H*) and flavone synthesis II (*GtFSII*) genes were isolated from *Gentiana triflora* and introduced into tobacco. *GtF3'H* transformation increased anthocyanin synthesis and flower color intensity, while *GtFSII* transformants had reduced anthocyanin (Nakatsuka *et al.*, 2006a, b).

Generally, carotenoids have received less attention than flavonoids in ornamental species; Davies *et al.* (2003) discussed some of the difficulties of targeting carotenoids. An interesting concept is the introduction of genes for green fluorescent protein (*gfp*) into flowers to generate fluorescent colors when the flowers are irradiated with UV or blue light (Mercuri *et al.*, 2001). Whilst such *gfp* expressing plants are novel in their own right, their longer term value may be questionable.

Floral scents are important in attracting pollinators and enhancing the aesthetic appeal of cut flowers. Loss of floral scent is one of the detrimental features of the conventional breeding of ornamentals, since scents are generally complex mixtures of mainly low molecular weight terpenoid, phenylpropanoid, and benzenoid compounds. Dudareva and Pichersky (2006) discussed the implications of loss of scent, but indicated that it is feasible to engineer plants to synthesize and to emit volatiles from their flowers. These authors presented a comprehensive list of the genes that have been isolated and characterized that are involved in the synthesis of volatile compounds. It is interesting to note that a circadian emission of scents is common in many plants.

Alteration of existing biosynthetic pathways, or the introduction of enzymes to generate novel compounds not normally present in host plants by reduction or up-regulation of metabolic flux through existing biosynthetic pathways, are possible strategies to engineer floral scents. The synthesis of volatiles depends upon the availability of substrates. Thus, petunia plants transformed with the rose alcohol acetyltransferase (*RhAAT*) gene were able to use phenylethyl alcohol and benzyl alcohol when these compounds were supplied in the culture medium, to synthesize the corresponding acetate esters. The latter were

not produced by flowers of nontransformed plants (Guterman *et al.*, 2006). It seems likely, because of the complex biosynthetic pathways involved, that multiple gene transfer may be essential for success, preferably with flower-specific promoters to drive transgene expression. Clearly, as Dudareva and Pichersky (2006) indicated, the genetic manipulation of floral scent is not a trivial issue and its longer term success will demand improved knowledge of existing biosynthetic pathways.

Postharvest vase life is extremely important, particularly for cut flowers. Since ethylene influences plant growth and development and triggers petal senescence, Shibuya and Clark (2006) considered the manipulation of ethylene biosynthesis and signaling to be one of the most promising approaches to improve crops through genetic engineering. Commercially, considerable use is made of chemical treatments to decrease the ethylene sensitivity of plants. However, the cloning of genes involved in ethylene biosynthesis and signaling now enables genetic manipulation to be an alternative approach. Thus, Shibuya and Clark (2006) summarized the gene constructs used in these two approaches in *Dianthus caryophyllus*, *Torenia fournieri*, and *Petunia hybrida*, with the CaMV 35S promoter driving gene expression in most of these constructs. Strategies to block ethylene biosynthesis include suppression of genes encoding 1-aminocyclopropane-1-carboxylic acid (ACC) synthase or ACC oxidase, and degradation of ethylene precursors by expression of genes not involved directly in ethylene synthesis. The gene for ACC deaminase from *Pseudomonas* has been used in this respect. Serek *et al.* (2006) concluded that an efficient way of suppressing ethylene signaling is by expressing a dominant mutant ethylene receptor gene, such as *etr1-1*, from *A. thaliana* in carnation, extending the vase life of cut flowers threefold. Manipulation of ethylene signaling by expression of the *EIN2* gene, using co-suppression or RNAi technology, has been applied to petunia (Shibuya *et al.*, 2004). As already indicated, the *ipt* gene from *A. tumefaciens* has been used to manipulate cytokinin biosynthesis in transgenic plants. An important commercial application of the expression of this gene results from its control by the SAG12 senescence-specific promoter from *A. thaliana*. The activity of a PSAG12-*ipt* construct occurred only during senescence, delaying this

process in flowers of transgenic plants of petunia (Chang *et al.*, 2003).

Whilst floral morphology is a prime target for genetic manipulation, leaves also contribute to the aesthetic appeal of ornamental plants. Leaf form demands control of cell division and polarity-dependent differentiation of cells. Kim (2006) listed the genes that control leaf shape, although there does not appear to be any publications in which such genes have been targeted to specific plants to induce a definite change in leaf morphology.

2.4.4 Improved tolerance to abiotic stresses

Drought and soil salinity are major problems in many parts of the world with salinity being common in marginal regions and areas of intense, irrigated agriculture. Borsani *et al.* (2003) discussed the ways of improving salt tolerance by transgenic technology, while Shen and Wang (2006) listed the genes exploited in transgenic technology to increase drought, salinity, and freezing tolerance in several crops. Such genes could also be introduced and expressed in horticulturally important plants. Drought response pathways are either dependent or independent of the stress-induced plant growth regulator, ABA. As in the case of cold tolerance, background information relating to the cloning of genes involved in ABA induced responses have been summarized (Shen and Wang, 2006). Similarly, the genes employed during the last decade to engineer cold tolerance in *A. thaliana* and crops such as alfalfa, tobacco, rice, and wheat, have been presented by these authors. It is interesting to note that some genes are multifunctional and confer resistance not only to drought, but also to salinity and freezing in plants. The choice of promoters, matrix attachment regions/scaffold attachment regions, the genes themselves and their terminators, are important parameters that must be considered during transformation, as are the sizes of gene constructs, the cellular targets for transgenes (nuclear/organelle), and the procedures for selection of transgenic plants.

Improved cold tolerance results in increased productivity and quality of horticultural plants, since cold causes considerable economic losses, particularly when plants are cultivated outside

their normal geographical range. Chilling injury occurs above 0°C, while freezing stress is associated with temperatures below 0°C because of ice crystal formation within cells. The extent of chilling injury depends on the species, the stage of plant development, the organs, and the duration of chilling. Physiological changes associated with the response to chilling include alteration in membrane lipids, inhibition of photosynthesis, photo-oxidative damage, and oxidative stress (Park and Chen, 2006). Freezing injury is generally more easily recognized with desiccation or burning of foliage, necrosis, and death. Damage is frequent on early flowering trees, as in members of the Rosaceae. Park and Chen (2006) provided a comprehensive table summarizing the genes already used to introduce chilling tolerance into a range of target plants. Interestingly, expression of the *ipt* gene under a cold-inducible promoter, *cor15a*, from *A. thaliana* prevented leaf senescence in petunia and chrysanthemum under storage in dark and cold conditions (Khodakovskaya *et al.*, 2005). Transformation technology to introduce cold tolerance into plants is restricted to some of the major crops and ornamentals such as petunia, although it is likely that this technology will be applied to other ornamental plants in the future.

The timing of vegetative growth and the initiation of flowering are governed by parameters such as day length, light quality, particularly the red to far-red ratio, and temperature. Consequently, manipulation of growth conditions is often required to ensure plant production for the consumer market at the required time. Genetic manipulation of plants may be an alternative means of circumventing the need to alter growth conditions. For example, Nie *et al.* (2006) introduced, by *Agrobacterium*-mediated gene delivery, the meristem identity gene *API* from *A. thaliana* into protocormlike structures of the orchids *Dendrobium phalaenopsis* and *D. nobile*. Manipulation of endogenous phytochromes is an energy-efficient strategy for modulating plant development and can be instigated at any time of the year (Franklin and Whitelam, 2006). Genes have been identified that control plant responses to light quality and duration (Frankhauser and Stainger, 2002). Expression of phytochrome biosynthesis (*PHY*) genes has been used to change the time of flowering in aster (Wallerstein *et al.*, 2002). In addition to modifying development in

this way, alteration of phytochrome biosynthesis may also affect plant stature, but with little effect of transgene expression on other plant characteristics, as in the expression of the tobacco *PHYB1* gene in chrysanthemum (Zheng *et al.*, 2001).

2.4.5 Disease resistance

Diseases induced by fungi, bacteria, and viruses cause major losses of all crop plants, including ornamentals, and reduce plant quality, which is evident at the market stage (Hammond *et al.*, 2006). Indeed, complete crop losses may occur due to viral and fungal infections. The transformation of ornamental plants for disease resistance has lagged behind that of major field crops, this being related to the broad spectrum of genera exploited for the cut flower market. Hammond *et al.* (2006) reviewed the literature pertaining to the approaches for engineering ornamental plants for pathogen resistance. Approaches for virus resistance include strategies that exploit viral coat protein genes in sense and antisense constructs, replicase sense viral genes, defective interfering RNA and DNAs, ribozymes, antiviral peptides, ribonucleases, and ribosome-inactivating proteins. Similarly, approaches for inducing fungal resistance into ornamental plants include the use of ribosome inactivating proteins, expression of plant and fungal chitinases, glucanases, thaumatins, and thionins. Plants transformed for fungal resistance include petunia, carnation, African violet, and rose. The latter, a popular cut flower globally, has been engineered, for example, for resistance to leaf black spot induced by *Diplocarpon rosae* using a rice chitinase gene (Marchant *et al.*, 1998). A similar technology may be adopted for other fungal pathogens that incite leaf spot diseases and cankers. Approaches to induce bacterial resistance involve transformation with genes for antimicrobial peptides and proteins, enzymes that detoxify or desensitize plants to bacterial toxins, and genes that enhance the natural disease resistance of plants. Wen *et al.* (2006) showed that chestnut rose (*Rosa roxburghii*) is resistant to powdery mildew, the most destructive fungal disease of rose, and that this plant is an excellent source of resistance to the fungus that can be exploited in rose breeding. Root-

knot nematodes account for considerable losses, particularly of field-grown woody ornamentals. Atkinson *et al.* (2003) indicated that a strategy that combines partial host plant resistance and partial transgenic resistance by a cysteine protease inhibitor may confer full nematode resistance.

2.4.6 Phytoremediation

The removal of toxic pollutants, such as phenol and chlorophenol, represents an important aspect of environmental improvement in which ornamental plants may play a key role, especially in the future. In this respect, de Araujo *et al.* (2006) evaluated the ability of several plant genera to accumulate pollutants and suggested, from their results, that the ornamental plant *Solanum aviculare* is an excellent candidate for exploitation in this way.

2.5 Plastid Engineering

In general, transformation studies have targeted the nuclear genome of recipient cells. However, it is likely that the transformation of plastids will assume considerably more importance as plastome engineering progresses from model systems, such as tobacco, to major crops (Maliga, 2003). In recent investigations, Li *et al.* (2006b) used biolistics to transform tobacco chloroplasts with the plastid expression vector pTRVP1 containing the foot-and-mouth disease virus *VPI* gene and the selectable *aadA* marker gene for resistance to the antibiotics streptomycin and spectinomycin. The advantages of plastid transformation compared to nuclear transformation, include high foreign protein synthesis in plastids and the absence of epigenetic effects in regenerated plants (Bock, 2001; Daniell *et al.*, 2002). Most transplastomic plants have been generated by particle bombardment of leaf tissues (Klaus *et al.*, 2003), although DNA uptake into isolated protoplasts has also been employed. The former procedure negates the requirement for labor-intensive protoplast-to-plant systems. The merit of plastid engineering is the apparent lack of transmission through pollen of transgenes to nontransformed plants of the same or different genera or species (Ruf *et al.*, 2001), although Stegemann *et al.* (2003)

demonstrated that escape of genetic material from chloroplasts to the nucleus occurs more frequently than was once believed. This DNA transfer may contribute to intraspecific and intraorganismic genetic variation.

2.6 Generation of Marker-Free Transgenic Ornamentals

Although the antibiotic resistance markers commonly used to select transgenic tissues and plants do not pose health risks to humans or animals, it is clear that legislation will demand the removal of such genes from transgenic plants. Currently, marker genes may be removed from transgenic plants by co-transformation followed by segregation of the resistance marker gene(s), homologous recombination and recombinase-mediated excision (Goldstein *et al.*, 2005). Klaus *et al.* (2004) summarized the procedures to generate marker-free transplastomic plants following DNA delivery to cells. An interesting concept was that reported by Tinoco *et al.* (2006) who used γ -radiation to physically remove marker genes from the nuclei of transgenic plants. Although demonstrated in soybean, there is no reason why this technology cannot be applied to ornamental plants. However, there is the possibility that novel mutations may be introduced by this approach.

2.7 Somaclonal Variation in Tissue Culture-Derived Plants: A Simple Form of Genetic Engineering?

Reliable procedures are available to combine interspecific and intergeneric traits by protoplast fusion, and the specific modification of genomes by transformation. Somaclonal variation, or protoclonal variation in the case of protoplasts, may be superimposed on these procedures. Such variation involves expression of naturally occurring genetic variation as a result of the culture procedure, or variation may be induced by the culture conditions *per se*. Such variation may be regarded as a simple form of genetic manipulation (Kantharajah and Golegaonkar, 2004) of relevance to crop improvement (Jain, 2001), and is frequently superimposed on the procedures of somatic hybridization and transformation. Several

examples of exposure of somaclonal variation exist in the literature relating to ornamental plants. Chaput *et al.* (1996) regenerated plants from leaf protoplasts of *Mentha* \times *piperata* and *M.* \times *citrata* and analyzed regenerants for their monoterpene composition. Their results revealed a decrease in menthone and menthol, but an increase in carvone in all protoplast-derived plants. Physiological changes have also been recorded in protoplast-derived plants, Pan *et al.* (2005) detecting more than a threefold variation in antioxidant activity in *Hypericum perforatum*. As in the case of mint, such chemically distinct germplines appeared morphologically normal.

It is not unexpected that most emphasis has been directed to changes in the morphology of ornamental plants. In a detailed investigation, Mizuhiro *et al.* (2001) reported that plants derived from cell suspensions of *Primula malacoides* cv. Lovely Tokyo and *P. obconica* cv. Aalsmeer Giant White, showed alterations in morphological characteristics compared to the plants from *in vitro*-germinated seeds. Specifically, such changes involved significantly reduced petioles and variation in floral morphology, particularly the lengths of pedicels and peduncles, inflorescence number and corolla size. In general, protoplast-derived plants formed compact inflorescences with multiple small flowers. Red pigmentation at the center of flowers was paler than in controls, while the periphery of some petals had green pigmentation. Such plant germplasm may be useful in future breeding programs to increase the phenotypic novelty in *Primula* species that are grown extensively as house and glasshouse pot plants. Somaclonal variation was also recorded in protoplast-derived plants of the Oriental hybrid lily cv. Acapulco, regenerated plants resembling their parents except for brown pigmentation of their anthers (Horita *et al.*, 2002).

Alstroemeria is a popular ornamental plant with demand for new cultivars. Subjecting isolated protoplasts to a period of culture may expose variation and contribute to enhancing the genetic base of this ornamental. In this respect, Kim *et al.* (2005) recognized variation in the morphology of leaves and flowers of *Alstroemeria* plants regenerated from protoplasts isolated from friable callus, including more elongate and rounded leaves, flowers with an increased number of petals, or petals with aberrant shapes. Flowers had either

increased pigmentation, or conversely, less intense pigmentation and an albinolike appearance. This protoplast-to-plant system for *Alstroemeria* is important not only in exposing genetic variation, but should facilitate the application of somatic hybridization to develop genotypes that are potential parents for breeding programs. Other workers have targeted *Iris fulva* and *Tricyrtis hirta*. In studies with the former genus, Inoue *et al.* (2006) regenerated tetraploid protoplast-derived plants, which the authors compared with diploid wild-type plants. Tetraploid plants had larger flowers of different morphology compared to parental plants. Subsequent experiments involved sexual hybridization of both diploid and tetraploid plants with *I. ensata* and *I. laevigata* to introduce the unique brown pigmentation from *I. fulva* into these other species. Nakano *et al.* (2006) studied somaclonal variation in *T. hirta* (Japanese toad lily), a popular pot and garden plant, and reported the regeneration of tetraploid ($2n = 4x = 52$) individuals amongst the normal diploid plants ($2n = 2x = 26$). Tetraploid regenerants had several attractive features, including longer shoots, thicker stems, and larger flowers. Chen *et al.* (2006a) analyzed the genetic differences of 19 cultivars selected from somaclonal variants of *Syngonium podophyllum* and six other aroids using AFLP markers generated by 12 primer sets. The authors concluded that much of the plant material was genetically similar, and emphasized the need to search for greater genetic diversity in this genus.

Where maximum genetic change is required, somaclonal variation provides a useful adjunct to the more technologically demanding approaches of transformation and somatic hybridization. Importantly, somaclonal variation does not require information of the genetic basis of specific traits, does not involve knowledge or practice of recombinant-DNA techniques, and may be exploited through simple routine culture procedures.

3. CONCLUDING REMARKS

Increased understanding of the genes involved in flowering will be of considerable benefit in floriculture, but interaction between biotechnological approaches and conventional plant breeding will be essential to improve ornamental crops

with the minimum of inputs (Giovannini, 2006). Brand (2006) emphasized that there still exists a considerable number of technical challenges of generating transgenic ornamental plants. However, the greatest challenge to realizing the potential benefits of transgenic technology remains the difficulty of gaining public acceptance of genetically manipulated crops and the prohibitive costs of generating environmental impact data to gain regulatory clearance. Klingeman and Hall (2006) concluded that the issues relating to the genetic manipulation of ornamental plants have been overshadowed by the debate on genetically manipulated foods. Studies by the same group involved surveys of the perception of gardeners to the effects of genetically manipulated ornamental plants on the environment and human health (Klingeman *et al.*, 2006). Participants stressed the need for genetically manipulated plant products to be clearly labeled at their point of sale. Undoubtedly, there is a requirement to improve consumer knowledge of genetically manipulated products and, likewise, of scientists to understand consumer perception and acceptance, since there remains a critical knowledge gap at the present time. Perhaps, as Klingeman *et al.* (2006) suggest, genetically manipulated ornamentals may play a crucial role in bringing positive public attention to the products of current biotechnology.

1. INTRODUCTION

Turfgrasses are grasses that provide vegetative ground cover, which is usually mowed routinely. Turfgrasses are used worldwide for lawns of home and office buildings, athletic fields, other recreational facilities, and roadsides. In the United States, there are more than 50 000 000 lawns and 14 000 golf courses and the turfgrass area was estimated in 1990 to be 30 million acres (12 million hectares) (Emmons, 1995). The turfgrass industry is a multibillion dollar a year business. Turfgrasses consist of a remarkably diverse group of species, mostly perennial grasses from the *Poa* family, which are selectively used based on the applications and/or environmental conditions. In general, based on their origins and geographical distributions, turfgrasses can be divided into two groups: cool-season grasses and warm-season grasses. Major cool-season turfgrasses include tall fescue, Kentucky bluegrass, perennial ryegrass, creeping and colonial bentgrasses, and fine fescues. Warm-season grasses used for turf contain bermudagrass, St. Augustinegrass, centipedegrass, Japanese lawngrass, buffalograss, seashore paspalum, and bahiagrass. Most of the cool-season grasses are propagated by seeds while a majority of the warm-season grasses are vegetatively propagated. Many of these species can also be used as forage crops.

Tall fescue (*Festuca arundinacea* Schreb.) is an outcrossing, allohexaploid species, with $2n = 6x = 42$. The genome size of tall fescue is estimated as 7.5×10^9 bp $1C^{-1}$. Tall fescue is of bunch-type growth and primarily spreads by tillering. It is more tolerant to heat and drought among the cool-season grasses and is widely used in the transition zone and the southern regions of the cool season zone. Tall fescue is also an important forage crop (Meyer and Watkins, 2003).

Kentucky bluegrass (*Poa pratensis* L.) is the most widely used turfgrass in the cool-season zone, and spreads with strong rhizomes to produce a dense turf. The reproduction mode and the cytology of Kentucky bluegrass are complicated issues. Kentucky bluegrass is aneuploid and produces seeds both asexually through apomixes and sexually. The level of apomixes among cultivars could vary from 25% to 96%, and the chromosome numbers within the species range from 24 up to 124 (Huff, 2003). The chromosome number among somatic cells within a genotype could vary too. An average chromosome is estimated to be 0.13–0.14 pg (picogram) of DNA (Huff, 2003) or approximately 0.13×10^9 bp/chromosome, and the genome size varies according to the chromosome numbers. A popular cultivar, Midnight, which has the chromosome number of 58–62, was estimated to be approximately 4.1×10^9 bp $1C^{-1}$.

Perennial ryegrass (*Lolium perenne* L.) is an outcrossing species although forced selfing can be achieved (Thorogood, 2003). It is diploid with $2n = 2x = 14$, and has an estimated genome size of approximately $2.1\text{--}2.5 \times 10^9 \text{ bp } 1\text{C}^{-1}$. It has a bunch-type growth habit, and is often a choice for athletic fields for its good wearing resistance. Perennial ryegrass is also widely used for winter overseeding of warm-season grass turf in the subtropical zone partially because of its rapid establishment.

Creeping bentgrass (*Agrostis stolonifera* L. or *Agrostis palustris* Huds.) has a fine texture and tolerance to mowing as low as 3 mm. Requiring high maintenance, the stoloniferous growth habit of creeping bentgrass provides carpetlike, soft, dense sod, and is mostly used for high quality turf on golf course putting greens, tees, and fairways. The outcrossing creeping bentgrass is allotetraploid with $2n = 4x = 28$ (Warnke, 2003) and has an estimated genome size of $2.7 \times 10^9 \text{ bp } 1\text{C}^{-1}$.

Colonial bentgrass (*Agrostis capillaris* L. or *Agrostis tenuis* Sibth.) is mostly used as a fairway grass and for erosion control. Outcrossing is the primary mode of sexual reproduction. The species is allotetraploid with $2n = 4x = 28$ (Ruemmele, 2003) with an estimated genome size of $2.8 \times 10^9 \text{ bp } 1\text{C}^{-1}$ (based on Bonos *et al.*, 2002).

Fine fescues are a group of fine-leaved *Festuca* species, containing two main species complexes: the red fescue (*F. rubra*) complex and the *F. ovina* complex (Ruemmele *et al.*, 2003). Being important turfgrasses in Europe and the United States, fine fescues are mostly used as turf in dry, shady, and low-fertile soils. Fine fescues are primarily open-pollinated species. The chromosome number of *F. rubra* complex species is $2n = 28, 42, 56$, and 70 with most of the plants being hexa- or octoploids, whereas *F. ovina* complex is $2n = 14, 28$, or 42. A hexaploid hard fescue (*Festuca trachyphyllas* or *Festuca longifolia*) cultivar Aurora in this complex has an estimated genome of $6.1 \times 10^9 \text{ bp } 1\text{C}^{-1}$.

Turf-type bermudagrass mainly includes common (or seeded) bermudagrass (*Cynodon dactylon* (L.) Pers. var. *dactylon*), a fertile tetraploid ($2n = 4x = 36$) species, and the interspecific hybrid (*C. dactylon* \times *Cynodon transvaalensis* Burt-Davy), a sterile triploid ($2n = 3x = 27$) (Taliaferro, 2003). The genome sizes of the two are estimated to be $0.94 \times 10^9 \text{ bp } 1\text{C}^{-1}$, and $0.66\text{--}0.78 \times 10^9 \text{ bp } 1\text{C}^{-1}$,

respectively. Hexaploid ($2n = 6x = 54$) of *C. dactylon* was also reported (Hanna *et al.*, 1990). Bermudagrass is the most important warm-season turfgrass found from temperate to tropical regions and forms good quality turf. The vegetatively propagated hybrid cultivars Tifgreen, Tifway, and the new TifEagle are widely used in golf greens and fairways in the warm-season zone. Common bermudagrass is outcrossing and propagated by seeds.

St. Augustinegrass (*Stenotaphrum secundatum* (Walt.) Kuntze) is a major turfgrass species in subtropical and tropical regions. In 2001, 70% of the lawns grown in Florida were St. Augustinegrass. The grass spreads by branching stolons and, in general, has coarse leaves. St. Augustinegrass is vegetatively propagated. Although artificial crossing can be readily performed, attempts for seed propagation were not successful. St. Augustinegrass is often $2n = 2x = 18$, although sterile triploid ($2n = 3x = 27$) and aneuploid were also reported (Busey, 2003). The genome size of a diploid cultivar, Raleigh, was estimated to be $0.52 \times 10^9 \text{ bp } 1\text{C}^{-1}$.

Centipedegrass (*Eremochloa ophiuroides* (Munro) Hack.) is a turfgrass species requiring only low maintenance and still provides acceptable turf quality (Hanna and Liu, 2003). It spreads by stolons, and is used in lawns and roadsides. The grass is seed propagated with $2n = 2x = 18$ chromosomes. The genome size of centipedegrass is $0.8 \times 10^9 \text{ bp } 1\text{C}^{-1}$.

Japanese lawngrass (*Zoysiagrass japonica*) is a turfgrass used for lawns, golf fairways, and athletic fields. It spreads by rhizomes and stolons, and can be either vegetatively or seed propagated. The chromosome number of the species is mostly reported as tetraploid with $2n = 4x = 40$ although diploidy was also recorded (Engelke and Anderson, 2003). The tetraploid genome size was estimated as $0.42 \times 10^9 \text{ bp } 1\text{C}^{-1}$.

Buffalograss (*Buchloe dactyloides* (Nutt.) Engelm) is a native North American grass used extensively as a turfgrass. Requiring minimum care, the grass spreads by branching stolons, is drought tolerant, and has excellent erosion control. Being a warm-season grass, buffalograss is also quite cold tolerant. Buffalograss is a dioecious species with separate male and female flowers that often occur in separate plants. The grass is mostly propagated vegetatively, and sometimes

by seeding (Riordan and Browning, 2003). Di-, tetra-, and hexaploidy ($2n = 2x, 4x, 6x = 20, 40, 60$) have been reported in buffalograss. Cultivar 609 is a tetraploid with a genome size of 0.77×10^9 bp $1C^{-1}$.

Seashore paspalum (*Paspalum vaginatum* Swartz) is a very unique, good-quality turfgrass species. It has high tolerance to salinity, drought, waterlogging, and low light intensity; adapts to a wide range of pH (3.6 to 10.2); and requires low maintenance (Duncan, 2003). It has been used as a salt-tolerant turfgrass in golf courses, sports fields, and for general landscaping, as well as utility turf for erosion control at coastal regions. The grass spreads by stolons and rhizomes, is outcrossing, but propagated vegetatively. Seashore paspalum is predominantly diploid with $2n = 2x = 20$ although tetra- and hexaploidy were reported. The genome size of the grass is not determined.

A chapter in the series is dedicated to bahiagrass (*Paspalum notatum* Flugge). Thus, the species would not be further discussed in this chapter.

Unless otherwise specified, the genome sizes were estimated based on the nuclear DNA content of individual species reported by Arumuganathan *et al.*, 1999, and the information that 1 pg DNA $\approx 0.965 \times 10^9$ bp (Arumuganathan and Earle, 1991).

Methodical turfgrass breeding probably started around the turn of the 20th century, and was substantially intensified in the past few decades (Casler and Duncan, 2003). The passage of the Plant Variety Protection (PVP) Act in the 1970s by the US Congress greatly encouraged and inspired the private businesses in the United States to breed new crop cultivars, including those of turfgrasses. A more uniform, dense turf with finer and greener leaves is a major target trait for improvement in turfgrass breeding. In addition, it should be realized that, although turfgrasses arose from natural habitats, the environments for them to be used as turf are “human-defined”, and often much more stressful than their original habitats, including many biotic and abiotic stress factors (Casler and Duncan, 2003). Thus, main breeding efforts are also toward resistance to (mostly fungal) diseases and insects, and tolerance to drought, extreme temperatures, shade, and in some cases, mowing. Recurrent selection of a population resulted from intercrossing of several individual parent clones, when possible, is probably the mostly

used approach for new cultivar development in turfgrass species. Interspecific hybridization and irradiation mutagenesis also play important roles in turfgrass breeding (Casler and Duncan, 2003). Transgenic technology was first applied to turfgrasses in the early 1990s, and so far transgenic plants have been successfully generated in nearly a dozen turfgrass species. Transgenic technology can break the barriers of gene exchange between species, and even kingdoms. It also can up- or down-regulate an individual endogenous gene for improvement of trait(s). For example, an herbicide or disease resistance gene of bacterial origin is readily introduced into a turfgrass species using the technology while no such gene can be found in the germplasm pool of the particular species. However, because of the perennial growth habit of turfgrasses and the outcrossing nature of most of the turfgrass species, the risk of transgene escape is a major concern in releasing transgenic turfgrass cultivars. Since tissue culture is usually a prerequisite for successful genetic transformation of turfgrasses, we will examine the achievements in tissue culture of various turfgrass species first in the chapter, which will be followed by the reported successes in transformation technologies in turfgrasses, improved traits by genetic transformation, regulatory issues on release of transgenic turfgrass, and future perspectives of turfgrass improvement through biotechnology.

2. GENETIC TRANSFORMATION OF TURFGRASSES

2.1 Tissue Culture Studies of Turfgrasses

With few exceptions (Clough and Bent, 1998), almost all plant transformation has to go through a tissue culture stage to deliver genes to embryogenic cells and to eventually regenerate transgenic plants from those cells. Thus, optimization of tissue culture responses of a plant species, especially improvement of regeneration ability, often plays a key role in the success of transformation efforts. Although not all the turfgrass species mentioned above have been transformed, tissue culture studies have been reported for each of them. In addition to obtaining transgenic plants, tissue culture also serves purposes such as rapid propagation of plants or creation of somaclonal variation

for breeding efforts (Brown and Thorpe, 1995). Tissue culture responses are generally affected by genotype and explant type of the species, the composition and supplements of the culture media, the phytohormones added in the media, and, sometimes, other factors. In the following description, we try to highlight the major approaches and the accomplishments in tissue culture found in the literature for each major turfgrass species, so the readers can have an historical view of the progresses in the field.

Krans (1981) obtained calli of tall fescue by culturing mature caryopses at 5 mg l^{-1} 2,4-dichlorophenoxyacetic acid (2,4-D), and plantlets from regeneration medium containing 0.01 mg l^{-1} 2,4-D and 0.2 mg l^{-1} kinetin. Lowe and Conger (1979) cultured mature embryos of tall fescue (cv. Kentucky 31) on Murashige and Skoog (MS) medium (Murashige and Skoog, 1962) containing 9 mg l^{-1} 2,4-D and observed almost 100% callus induction. About 18% calli regenerated shoots and the regeneration ability declined along with subculture on 5 mg l^{-1} 2,4-D. Dale and Dalton (1983) cultured immature inflorescences (1–20 mm in length) in MS medium containing 2 mg l^{-1} 2,4-D with or without 0.2 mg l^{-1} 6-benzylaminopurine (BAP), and obtained 10.2 plantlets per inflorescence. The shoots could directly form from floret primordia or through callus. Eizenga and Dahleen (1990) studied culture responses of partially emerged inflorescences of various genotypes within cv. Kentucky 31 and observed significant variations among genotypes in callus induction and plant regeneration. The explants were cultured on Schenk and Hildebrandt (SH) (Schenk and Hildebrandt, 1972) medium with various auxins. Callus production was significantly higher when 2,4-D was used as the auxin source over para-chlorophenoxyacetic acid (pCPA) or 2,4,5-trichlorophenoxyacetic acid (2,4,5-T). Bai and Qu (2000) compared tissue culture responses of mature caryopses among 25 turf-type tall fescue cultivars on MS medium containing 9 mg l^{-1} 2,4-D, and observed a wide range of callus induction rates (from 4.4% to 51.9%). The callus regeneration rates were from 16.7% to 58.8% on MS regeneration medium containing 2.5 mg l^{-1} BAP. The overall plant regeneration rates (regeneration callus over explants cultured) varied from 1% to 22%, reflecting substantial differences among cultivars. In another report, the same group studied effects

of medium supplements on culture responses of an elite turf-type cultivar, Coronado (Bai and Qu, 2001a). They found inclusion of BAP (0.1 mg l^{-1}) in callus induction medium significantly improved callus regeneration for explants of immature embryo and mature caryopses. Casein hydrolysate (CH), L-proline, and myo-inositol improved callus induction of immature embryos but not mature caryopsis. These supplements had no effect on callus regeneration. Longitudinally slicing mature caryopses into two halves improved their callus induction by three- to sixfold. The optimal supplement combination for the sliced caryopses was 5 or 9 mg l^{-1} 2,4-D and 0.1 mg l^{-1} BAP, which yielded about 30% overall plant regeneration. Dalton (1988) developed suspension cultures in MS-based medium from embryogenic calli induced from chopped mature embryos of tall fescue. Up to 0.4% of protoplasts isolated from the suspension culture formed colonies when cultured in glucose-containing medium, and more than 100 colonies formed green shoots. By using agarose bead method and nurse culture, Takamizo *et al.* (1990) also obtained green plants from protoplasts isolated from a suspension line that was derived from a young leaf-base culture. In another direction, Kasperbauer *et al.* (1980) obtained anther-derived haploid plants from culture of panicle sections containing several florets after a cold temperature pretreatment. Later on, doubled haploid plants were recovered after subculturing the haploid calli for 15 weeks to reach an “aged” stage and then transferred to a regeneration medium (Kasperbauer and Eizenga, 1985). Somaclonal variation among the regenerated tall fescue plants was observed in traits such as total biomass, seed yield, and leaf shape (Roylance *et al.*, 1994; Bai, 2001). Garcia *et al.* (1994) reported great alteration in flowering response among regenerated plants: some plants flowered without vernalization treatment, and a plant did not flower after 2 years with vernalization. Chromosome number usually did not change but chromosome aberrations were observed. Since maintenance of suspension culture is labor intensive and the regeneration ability of the suspension lines usually declines along with time, Wang *et al.* (1994) explored conditions of cryopreservation of the suspension cells, and found that high-osmotic preculture and cryoprotectant containing 10% dimethyl sulfoxide (DMSO) and

0.5 M sorbitol were the most suitable for storage of tall fescue suspension cells in liquid nitrogen. Up to 71% of the cells could regrow after cryopreservation, and embryogenic suspensions were re-established. Bai (2001) found that a cryoprotectant recipe used for rice and barley, which contains 0.5 M DMSO, 0.5 M glycerol and 1 M sucrose, was the best among the tested, and did not require osmotic preculture treatment. The cells, after being stored for 30 days in liquid nitrogen, increased by 65% in fresh weight after 4 weeks of culture on a solid medium.

Krans (1981) reported callus induction and root formation of Kentucky bluegrass. McDonnell and Conger (1984) used mature embryos as explants and a modified SH medium, and observed that 20 μ M dicamba or 60 μ M picloram was most effective in callus growth and in inhibiting leaf growth. The regeneration rates were very low (0–3.1%) but were improved by culturing at a low temperature (15 °C), and further enhanced (up to 18%) by a week of cold treatment (4 °C) before transferring to the regeneration medium. Boyd and Dale (1986) used mature embryo culture to evaluate 50 cultivars for their callus induction and plantlet regeneration ability, and found great variations among the cultivars. The authors considered that MS basal medium supplemented with 0.2 mg l⁻¹ 2,4-D, 0.1 mg l⁻¹ BAP, 100 mg l⁻¹ CH, and 25 g l⁻¹ sucrose was good for both callus growth and plantlet regeneration. Wu and Jampates (1986) obtained plantlets from calli induced from shoot tips. Van Der Valk *et al.* (1989) studied tissue culture responses of 15 cultivars, and found that calli from immature inflorescences of 14 cultivars regenerated plantlets and the regeneration rates were often over 50%, whereas regeneration of calli from mature caryopses were very low: plantlets were recovered from only 3 cultivars with regeneration frequencies below 3%. Van Ark *et al.* (1991) found regeneration frequency was doubled when Gelrite was used as a gelling agent over agar, and abscisic acid (ABA) enhanced somatic embryogenesis although regeneration rate was not affected. In 1995, two groups reported high frequency of regeneration from mature caryopsis-induced calli by including BAP in the callus-induction medium (Griffin and Dibble, 1995; Van Der Valk *et al.*, 1995). Ke and Lee (1996) investigated culture responses of tissues from young seedlings, and observed that calli

induced from coleoptiles had highest regeneration frequency (32%) when the regeneration medium contained 0.2 mg l⁻¹ picloram and 0.01 mg l⁻¹ α -naphthalene acetic acid (NAA). Salehi and Khosh-Khui (2005) observed that the callus induction rate from mature caryopses was 100% when 40 μ M (8.85 mg l⁻¹) 2,4-D was added to the induction medium and 100% regeneration was achieved when 60 μ M 2,4-D (13.3 mg l⁻¹) and 12.5 μ M (2.8 mg l⁻¹) of BAP was used in the regeneration medium. Hu *et al.* (2006) cultured shoot apices of seedlings in a medium containing low 2,4-D (0.9 μ M or 0.2 mg l⁻¹) and 8.9 μ M (2 mg l⁻¹) BAP to induce multiple shoot clumps, which came from meristematic cell clumps originated from embryonic axis, especially the hypocotyls in the culture. In addition, green plantlet regeneration from embryogenic suspension cell culture (Nielsen and Knudsen, 1993) and protoplast (Nielsen *et al.*, 1993) were reported. The suspension lines were derived from calli induced from mature caryopses or mature embryos of cv. Geronimo. Using the agarose-embedding technique, the protoplast plating efficiencies were demonstrated to vary from 0.004% to 1.5%, and 0.4% to 2.7% of the protoplast-derived microcolonies were able to regenerate.

Krans (1981) also first reported perennial ryegrass plants regenerated through tissue culture using an approach similar to he did with tall fescue. With mature caryopses as explant, Torello and Symington (1984) found subculture of calli on medium containing 5 mg l⁻¹ of 2,4-D was preferred over 10 mg l⁻¹, with 0.1 mg l⁻¹ BAP in regeneration medium being optimal for shoot regeneration. The same group (Zaghmout and Torello, 1992a) reported advantages to include cefotaxime (60–200 mg l⁻¹) in culture medium for improved green plantlet formation. The authors observed that “cefotaxime reduced the inhibitory effect of 2,4-D on precocious germination of somatic embryos.” Dale and Dalton (1983) cultured immature inflorescences (1–20 mm in length) in MS medium, and found 50% more shoots were formed directly or through callus when the medium containing 2 mg l⁻¹ 2,4-D was supplemented with 0.2 mg l⁻¹ BAP and 100 mg l⁻¹ casein hydrolysate (CH). In mature caryopsis culture, Bradley *et al.* (2001) observed substantial variations in callus induction (2.3–21%) and regeneration (0–58%) among 13 elite turf-type

cultivars. Slicing of the caryopsis longitudinally increased callus induction rate by more than fivefold when 2,4-D level was 2 mg l^{-1} . Inclusion of BAP (0.5 mg l^{-1}) in callus induction and subculture medium enhanced its regeneration rate by more than threefold. Salehi and Khosh-Khui (2005) observed 98% callus induction rate from mature caryopses (cv. Barbel) when 2,4-D concentration in the callus induction medium was as high as $150 \mu\text{M}$ (33.3 mg l^{-1}). They obtained 100% callus regeneration when the regeneration medium contained $60 \mu\text{M}$ 2,4-D (13.3 mg l^{-1}) and $7.5 \mu\text{M}$ (1.7 mg l^{-1}) BAP. In suspension culture, Olesen *et al.* (1996) examined suspensions from 21 commercial varieties and could regenerate green plantlets from 18 of them. In a multifactorial experiment to optimize suspension culture conditions, Altpeter and Posselt (2000) observed that replacement of sucrose by maltose, dicamba by 2,4-D (5 mg l^{-1}), and a stepwise increase of BAP to 0.25 mg l^{-1} enhanced green shoot regeneration ability of the suspensions, but addition of CH did not. Using this medium, together with the best-performed genotype, L6, 488 green plantlets were regenerated from per gram fresh weight suspensions. Dalton (1988) reported recovery of green plantlets from protoplast culture of perennial ryegrass without agarose embedding and nurse culture. Creemers-Molenaar *et al.* (1989) observed that protoplast from "nonmorphogenic" suspensions had higher plating rate than the ones from "morphogenic" suspensions, and also recovered green plantlets from protoplast culture. The same group (Creemers-Molenaar *et al.*, 1992) reported that conditioned medium was "indispensable" for plating of protoplasts from younger, regenerable suspensions. O-acetylsalicylic acid and some antioxidants also helped improve plating efficiency. Wang *et al.* (1993) established single genotype-based embryogenic suspension lines and cultured protoplasts using agarose bead and nurse cells. Protoplasts from cryopreserved suspensions performed similarly to the ones isolated from the fresh suspensions and dozens of green plantlets were regenerated. Moreover, Olesen *et al.* (1988) reported successful anther culture of perennial ryegrass after cold pretreatment without nurse culture, and found that recovery of green plantlets were mostly from 2 genotypes. Perezvicente *et al.* (1993) cultured vegetative apices ($0.05\text{--}0.3 \text{ mm}$) consisting of the meristematic dome and 1–4 leaf

primordia in MS medium containing 0.01 mg l^{-1} 2,4-D and 0.2 mg l^{-1} kinetin under dim light condition. About 99% of the explants formed plantlets. Plants regenerated from suspension cell cultures of perennial ryegrass were compared to the seed-grown plants in the field (Stadelmann *et al.*, 1998). Quite often, the regenerated plants showed a delay in inflorescence emergence, a reduced seed yield, and other morphological variations. Sometimes, alterations in DNA sequences were detected by random amplified polymorphic DNA markers. Plants with similar or superior performance to the seed-grown plants were also observed.

Successful tissue culture of creeping bentgrass was first reported by Krans (1981) using caryopses as explants. The greatest callus induction came from cultures in medium containing 1 mg l^{-1} 2,4-D under light, or containing 1 mg l^{-1} 2,4-D and 0.01 mg l^{-1} kinetin in the dark. Calli cultured on 1 mg l^{-1} 2,4-D maintained good regeneration ability and the best regeneration medium contained 0.1 or 1 mg l^{-1} kinetin. Using a 24-week-old stock callus, Blanche *et al.* (1986) observed that callus growth was twice greater after being cultured for 12 or 24 days in suspension, whereas suspension culture greatly reduced plantlet formation. They also determined that the callus growth rate and regeneration frequency were correlated to the size of callus aggregates and the plating density. Zhong *et al.* (1991) evaluated various plant growth regulators on embryogenesis of creeping bentgrass caryopses culture, and observed that MS basal medium containing $30 \mu\text{M}$ (6.63 mg l^{-1}) dicamba and $2.25 \mu\text{M}$ (0.5 mg l^{-1}) BAP was optimal, in which 91% calli were embryogenic and over 80% of the somatic embryos formed plantlets after transferring to the regeneration medium. Terakawa *et al.* (1992) reported microcolony formation and 0.36% plating efficiency from protoplasts of creeping bentgrass, cv. Penncross, cultured in a conditioned medium. Thirty percent of the microcolonies formed green plantlets. Lee *et al.* (1996) developed an efficient system for protoplast isolation, culture and regeneration from 7 cultivars. Using feeder cells, the plating frequencies ranged from 0.05% to 0.32%.

Torello *et al.* (1984) observed different culture responses of mature caryopses of two cultivars in red fescue, and investigated the effects of auxin sources on callus growth. They found $20 \mu\text{M}$ (4.4 mg l^{-1}) 2,4-D was the best in callus

growth, and used 0.1 mg l^{-1} BAP for regeneration medium. In general, regeneration ability of a long-term callus culture declined. The same group found that addition of activated charcoal to the callus maintenance medium prior to callus transferring to the regeneration medium significantly enhanced the regeneration ability of calli cultured for over 5 years (Zaghmout and Torello, 1988). They believed that the activated charcoal could adsorb toxic levels of 2,4-D and other morphogenesis inhibitors. These authors later developed suspension cultures using a modified MS medium containing 4 mg l^{-1} 2,4-D and 3 g l^{-1} CH with the latter enhancing culture growth significantly. Removal of fast-growing, nonembryogenic cell clusters before initiation of suspensions was thought to be critical, and green plantlets were regenerated from the suspensions (Zaghmout and Torello, 1989). In addition, the same authors found that elevating sucrose level from 60 mM up to 120 and 180 mM in suspension as well as regeneration media helped restore regeneration potential of long-term suspension cultures, and increased green plantlet formation (Zaghmout and Torello, 1992b). Protoplasts were isolated from the embryogenic suspension cells and plated in agarose squares surrounded by nurse cells. The maximum plating efficiency was 1%. The microcolonies produced embryos, which germinated to form plantlets in regeneration medium (Zaghmout and Torello, 1990). Altpeter and Xu (2000) tested tissue culture responses of mature embryos from 7 turf-type red fescue cultivars, observed callus induction rates ranged from 57% to 78.4% in a medium containing 5 mg l^{-1} 2,4-D, and found significant difference in callus regeneration ability (from 0% to 22%) on a medium containing 0.1 mg l^{-1} 2,4-D and 0.1 mg l^{-1} BAP. Recently, Salehi and Khosh-Khui (2005) reported that very high 2,4-D concentration ($200 \text{ } \mu\text{M}$ or 44.4 mg l^{-1}) enhanced callus induction rate (78%) of red fescue (cv. Shadow), and a combination of $60 \text{ } \mu\text{M}$ (13.3 mg l^{-1}) of 2,4-D and $12.5 \text{ } \mu\text{M}$ (2.8 mg l^{-1}) of BAP resulted in the highest callus regeneration rate (34%) of red fescue.

The only report on colonial bentgrass tissue culture (Wang *et al.*, 2002) evaluated 14 MS-based culture media containing various phytohormones and other supplements for mature caryopses culture of cv. Exeter. Eleven media that contained 2,4-D as an auxin had high callus induction

rates (98–100%). In general, embryogenic callus induction was low. Although the best callus induction medium was the MS medium containing 5 mg l^{-1} 2,4-D and 500 mg l^{-1} L-proline, which had 100% callus induction and yielded 19% “embryogenic calli”, they regenerated poorly. On the other hand, the media containing dicamba (6.63 mg l^{-1}), BAP ($0.5\text{--}2 \text{ mg l}^{-1}$), and CH (500 mg l^{-1}) had low callus induction rates (20–37%), but relatively high embryogenic callus frequencies (6–10%), and the embryogenic calli were more regenerable. CH by itself seemed to promote callus regeneration. Media containing 2,4-D ($2\text{--}5 \text{ mg l}^{-1}$) and CH had 5–7% embryogenic callus formation and high regeneration rates from those calli.

In warm-season turfgrasses, callus induction of common bermudagrass was first reported by Krans (1981). Ahn *et al.* (1985) observed that calli had significantly more fresh weight when growing on N6 medium (Chu *et al.*, 1975) over the MS medium. The best culture conditions in the report were immature inflorescence of 0.5 cm in length on N6 medium containing 1 mg l^{-1} 2,4-D and 60 g l^{-1} sucrose, from which 84% of calli were embryogenic. Green plantlets were obtained from hormone-free N6 medium and, subsequently, grown to maturity. It seemed the explant type and age played an important role in recovering regenerated plants since no plantlets were regenerated when nodes, root tips, young leaves, mature caryopses or inflorescences longer than 1.5 cm were used as explants. A follow-up report from the same group demonstrated genotype dependence of the regeneration ability of the induced calli. In addition, a regenerable suspension cell culture was established (Ahn *et al.*, 1987). Artunduaga *et al.* (1988) investigated 2,4-D concentrations required by different genotypes of common bermudagrass for best embryogenic callus formation from immature inflorescence. While all the induction medium (a half-strength MS medium) also contained 1 mg l^{-1} indole-3-acetic acid (IAA), the authors found 1 mg l^{-1} 2,4-D was optimal for embryogenic callus formation from an accession while 3 mg l^{-1} was more suitable for two other accessions. Plantlets were regenerated from two out of the three accessions on a half-strength MS medium supplemented with 0.5 mg l^{-1} 2,4-D and 1 mg l^{-1} zeatin although about 90% of the plantlets from an accession were

albino. In another correspondence (Artunduaga *et al.*, 1989), the same group studied 2,4-D concentration and supplement of CH on culture responses of immature inflorescence of *C. dactylon* cv. Zebra. The maximum fresh weight and embryogenic callus induction came from the medium containing 3 mg l^{-1} 2,4-D and 200 mg l^{-1} CH. The albino plants were as high as 31% of the regenerated plants. Chaudhury and Qu (2000) observed that inclusion of 1 mg l^{-1} 2,4-D and very low concentration of BAP (0.01 mg l^{-1}) in the callus induction/subculture medium substantially improved the regeneration ability of the calli from common bermudagrass cv. Savannah and hybrid cv. Tifgreen. The effect was more obvious when younger immature inflorescences ($<0.75 \text{ cm}$) were used as explants. All 96 plantlets obtained were green and morphologically normal. Scanning electron microscopy (SEM) revealed embryogenesis was the major pathway for plantlet regeneration in bermudagrass. Li and Qu (2002) found that supplement of ABA ($2\text{--}5 \text{ mg l}^{-1}$) to the above BAP-containing medium further improved formation of somatic embryo clusters (SEC), and tracked the whole process of SEC formation microscopically over a period of 70 days. In addition, secondary somatic embryogenesis was observed in this species. Moreover, they found that bermudagrass plantlet regeneration was greatly enhanced by addition of GA_3 in the regeneration medium. Li and Qu (2004) further developed highly-regenerable callus lines, including suspension lines, by adjusting BAP level in the medium and carefully selecting calli. Salehi and Khosh-Khui (2005) tested a wide range of 2,4-D concentrations in MS callus induction medium for mature caryopsis culture of common bermudagrass (the cultivar was only identified as "California origin") and BAP concentrations in regeneration medium, and found that $40 \text{ }\mu\text{M}$ (8.85 mg l^{-1}) 2,4-D had 100% callus induction frequency, and $60 \text{ }\mu\text{M}$ 2,4-D (13.3 mg l^{-1}) and $7.5 \text{ }\mu\text{M}$ (1.7 mg l^{-1}) BAP led to 100% callus regeneration with 3.2 plantlets per piece of callus. The widely used hybrid bermudagrass cultivars, Tifgreen (Burton, 1964), Tifway (Burton, 1966), TifEagle (Hanna and Elsner, 1999), and TifSport (Hanna *et al.*, 1997), although all being *C. dactylon* \times *C. transvaalensis*, seem to be very divergent in their responses to tissue culture. Goldman *et al.* (2004b) reported 36% embryogenic callus induction rate from nodes

of TifEagle plants using an MS medium containing $4.5 \text{ }\mu\text{M}$ 2,4-D, $0.044 \text{ }\mu\text{M}$ BAP, and 40 g l^{-1} (instead of the routine 30 g l^{-1}) sucrose. In contrary, no embryogenic calli were produced from nodes of TifSport. The best culture of TifSport using very young immature inflorescence yielded 16% of embryogenic calli on the same medium. A great range of somaclonal variation, in terms of plant height, leaf width, leaf length, and number of stolons, was observed from regenerated plants of TifEagle, but not from TifSport. Tifway, on the other hand, may be the most recalcitrant cultivar among the four, with tissue culture responses more similar to a parent, *C. transvaalensis* (Chaudhury and Qu, unpublished data). Although calli were ready to be induced from vegetative tissues (nodes, internodes, and young leaves), and were not prone to browning, they were not regenerable. Severe browning, caused by secretion of phenolic compounds, was encountered when immature inflorescences were cultured, which resulted in little callus induction. Qu and Chaudhury (2001) overcame the problem by treating the inflorescence segments in liquid MS medium containing 0.2% L-ascorbic acid, an antioxidant, followed by culture on an MS callus induction medium supplemented with 6 g l^{-1} polyvinylpyrrolidone (PVPP), which is a polyphenol adsorbent. By doing so, calli were induced from over 50% of immature inflorescences smaller than 1.5 cm, and green plantlets were regenerated.

St. Augustinegrass tissue culture was first reported by Kuo and Smith (1993). Immature embryos isolated from inflorescences, 10–14 days after emergence from the sheath, of cv. Texas Common were cultured on MS medium supplemented with various concentration of 2, 4-D for callus induction. Calli induced on medium containing 1 mg l^{-1} 2,4-D grew faster than the calli on 5 mg l^{-1} 2,4-D medium, whereas no calli were induced on medium having 10 mg l^{-1} 2, 4-D. Four weeks later, the calli were subcultured on MS medium containing 0.5 mg l^{-1} 2,4-D and 0.25 mg l^{-1} kinetin for another 4 weeks before they were transferred to the MS medium supplemented with 0.25 mg l^{-1} 2,4-D and 0.5 mg l^{-1} kinetin. After 1–2 weeks, somatic embryos became obvious and shootlike structures were observed. The calli were then transferred to the hormone-free, half-strength MS medium for further growth of the plantlets. Approximately 33% of the induced calli were able

to regenerate plantlets. The authors considered it was critical to have timely transfer of callus at each stage for successful regeneration. Li *et al.* (2006) examined callus induction of 11 types of explants of St. Augustinegrass (cv. Raleigh) and the effect of BAP in callus induction medium. The explants were cultured on MS medium supplemented with 1 mg l^{-1} 2,4-D and various concentrations of BAP. Although they observed that five types of explants had high callus induction frequencies (71–100%), only calli from three kinds of explants were embryogenic and can regenerate plantlets. They are immature embryos harvested at various stages (3 days and 7–14 days) and young shoot base. However, the callus induction of the 3 days immature embryos was below 20%, and the regeneration rate of calli induced from young shoot base was under 10%. In general, addition of BAP in callus induction medium did not affect callus induction but significantly improved callus regeneration ability. The best combination the authors found were the use of 7–14 days immature embryo as explant and a callus induction medium (with 1 mg l^{-1} 2,4-D) supplemented with 0.5 mg l^{-1} BAP, which had 97.7% callus induction frequency and 47.6% regeneration rate. SEM study revealed details of somatic embryogenesis in the species. Approximately 8000 plants were regenerated in a breeding effort to induce somaclonal variations (Li *et al.*, submitted).

Tissue culture of Japanese lawngrass was first reported in 1989 (Alkhayri *et al.*, 1989; Asano, 1989). In Asano's report, calli were induced from 4-day-old seedlings cultured on a modified N6 medium containing various concentration of 2, 4-D or picloram. More fresh weight of callus was recovered from picloram-containing medium. Only 0.3% of calli developed embryogenic sectors, from which green plantlets were obtained on a hormone-free, half-strength MS medium. No obvious morphological variations were observed from the recovered plants. Protoplasts were isolated from callus lines and cultured in the same modified N6 medium supplemented with 5 mg l^{-1} picloram. Plating efficiency was about 20–30%, but no regeneration was observed. Alkhayri *et al.* (1989) had somewhat different observation. They cultured mature embryos separated from caryopses on MS or N6 medium with various 2,4-D concentrations. Over 90% of the explants produced calli in all treatments.

The best combination was MS medium with 1 mg l^{-1} 2,4-D; the calli had more fresh weight and higher regeneration frequency (42–59%) after transferred to 2,4-D-free regeneration medium. Calli from N6 medium did not regenerate. Asano *et al.* (1996) found that cytokinin, especially BAP and thidiazuron (TDZ), and thiamine HCl were essential for embryogenesis. In their presence, supplement of riboflavin or α -ketoglutaric acid, a key metabolic intermediate of TCA cycle, further enhanced formation of embryogenic calli. Inokuma *et al.* (1996) observed that LS medium (Linsmaier and Skoog, 1965) had been superior over MS or N6 medium in inducing embryogenic calli in this species. Protoplasts were isolated from the suspensions and the best plating efficiency was 0.15% in medium solidified with agarose. Green plantlets were recovered from the protoplast culture.

In vitro regeneration of buffalograss was first reported in 1997 (Fei *et al.*, 1997). Female immature inflorescences of cv. 609 were cultured in MS medium containing a combination of 2, 4-D ($1\text{--}4 \text{ mg l}^{-1}$) and BAP ($0\text{--}0.4 \text{ mg l}^{-1}$). Seventeen percent calli from medium containing 2,4-D only ($1\text{--}3 \text{ mg l}^{-1}$) regenerated shoots. Interestingly, no calli from BAP-containing medium regenerated. The tissue culture responses depended on genotype and the season when the inflorescences were harvested. Later on, the same group reported that inclusion of silver nitrate (10 mg l^{-1}) in the callus induction medium significantly improved embryogenic callus formation and subsequent regeneration for cultures of immature inflorescences from male plants of two genotypes but not the ones from female plants. The stimulatory effects were environment and genotype dependent (Fei *et al.*, 2000). In another correspondence (Fei *et al.*, 2002), the authors reported that lowering 2, 4-D concentration and addition of BAP enhanced shoot regeneration for 2-month-old calli induced on a medium containing $9 \mu\text{M}$ (2 mg l^{-1}) 2,4-D from male immature inflorescences of cv. Texoka. The best regeneration medium contained $2.25 \mu\text{M}$ (0.5 mg l^{-1}) 2,4-D and $0.44 \mu\text{M}$ (0.1 mg l^{-1}) of BAP, on which 36.4% embryogenic calli regenerated shoots. It was also found that gelling agent Gelrite significantly improved somatic embryo formation over agar. However, these effects also seemed to be genotype dependent since no such enhancement was observed for immature inflorescences collected

from female plants of genotype 315. In addition, embryogenic calli were obtained from leaf base and leaf segments of seedlings from germinating caryopsis of cv. Cody. The induction frequency was relatively low (around 10%) and depended on seedling age and the concentration of 2,4-D in the induction medium. Plantlets were recovered from the embryogenic calli (Fei *et al.*, 2001).

Seashore paspalum is a recently promoted turfgrass species and its tissue culture was not reported until 1997. Cardona and Duncan (1997) used immature inflorescences as an explant from 9 ecotypes of seashore paspalum. The explants were cultured on a medium consisting of the MS basal salts and B5 vitamins. In a factorial experiment designed to test the effects of growth regulators 2,4-D and BAP, it was observed that the effect of BAP or the interaction between BAP and 2,4-D was not significant in callus induction efficiency whereas the effect of 2,4-D was. Responses to 2,4-D concentrations varied among the ecotypes tested. However, a low concentration of 2,4-D (1 to 2 mg l^{-1}) was recommended for embryogenic callus formation. The callus first emerged about a week after culture initiation while “precocious” somatic embryos were observed 3 weeks later. Callus induction frequency varied from 0% up to 55%. Five-month-old calli were cultured on a half-strength MS medium containing different combinations of BAP and NAA for regeneration, and numerous green plantlets were recovered from all the ecotypes. Although the optimized combination of BAP and NAA varied among the ecotypes, the combination of 1 mg l^{-1} BAP with NAA between 0.5 and 2 mg l^{-1} often had the highest regeneration frequency. Ecotypes HI-1, Mauna Key, and PI299042 were among the best in regeneration ability.

Centipedegrass tissue culture was first reported by Krans’ lab (Krans, 1981; Krans and Blanche, 1985). One mg l^{-1} 2,4-D or 100 mg l^{-1} IAA was determined to be the optimal concentration for callus induction on MS medium based on fresh callus weight. Fresh callus weight from a single explant was greater using immature inflorescence than mature caryopses. When the calli were transferred to regeneration medium, either hormone free or containing 0.5 mg l^{-1} kinetin, plantlets were obtained with less than 1% of albinos. “Explant source had no affect on frequency or quality of plantlets.” Ma *et al.*

(2004) induced calli from mature caryopses on MS medium supplemented with 4.5 mg l^{-1} 2,4-D and 0.1 mg l^{-1} BAP, and subcultured them on MS medium containing 4 mg l^{-1} 2,4-D, 0.1 mg l^{-1} BAP, and 5 mg l^{-1} ascorbic acid. The MS regeneration medium included 2 mg l^{-1} BAP, 1 mg l^{-1} NAA, 5 mg l^{-1} CoCl_2 , and 0.5 mg l^{-1} TDZ. The regeneration frequency was over 90%. The authors thought that CoCl_2 , an ethylene inhibitor, helped in callus regeneration.

2.2 Development of Transgenic Turfgrass Plants

As in most monocot transformation cases, there are three major approaches to transform turfgrasses: protoplast (by polyethylene glycol (PEG) treatment or electroporation), particle bombardment (also known as microprojectile bombardment or the biolistic method, and can be performed with a Du Pont PDS-1000/He device or a particle inflow gun), or *Agrobacterium tumefaciens* infection. The most frequently used selection systems include *Escherichia coli* hygromycin B phosphotransferase gene (*hph* or *hpt*) and hygromycin B (*hyg B*) (Gritz and Davies, 1983), or *Streptomyces hygroscopicus* phosphinothricin acetyltransferase gene (*bar*) and bialaphos (active ingredient of herbicide Herbace[®]) or phosphinothricin (PPT or glufosinate, active ingredient of herbicides BastaTM, Liberty[®], Finale[®], and Challenge[®]) (Thompson *et al.*, 1987). The selectable marker genes are usually under control of cauliflower mosaic virus (CaMV) 35S promoter, rice *Act1* promoter, or maize *ubil* promoter. Quite often, the *E. coli* β -glucuronidase gene (*uidA* or *GUS*) (Jefferson *et al.*, 1987) or the jellyfish green fluorescent protein gene (*gfp*) (Chalfie *et al.*, 1994) is used as a reporter gene to help evaluate the transformation efforts. Polymerase chain reaction (PCR) and reporter gene expression are usually employed to preliminarily screen for putative transgenic plants. However, the genome integration of the transgene in the selection agent-resistant plants has to be confirmed by Southern blot analysis. The Southern hybridization patterns often help distinguish independent transformation events. Expression of the transgene should be demonstrated by

Northern and/or Western analysis, and/or the activity of the enzyme encoded by the transgene.

Wang *et al.* (1992) first reported tall fescue transformation by introducing DNA vectors through PEG treatment into protoplasts isolated from embryogenic suspensions. After transformation, the protoplasts were cultured with agarose bead-type method with nurse cells, and were later selected with either hyg B (200 mg l⁻¹) or PPT (100 or 200 mg l⁻¹). The transformation frequency ranged from 10⁻⁶ and 10⁻⁵. A total of 38 independent, morphologically normal transgenic plants were obtained. Plants with *bar* transgene were resistant to herbicide BastaTM. In another report, Ha *et al.* (1992) electroporated protoplasts and recovered regenerated transgenic plants with hyg B selection. They also demonstrated *GUS* reporter gene expression in the transgenic plants. The same group later (Penmetsa and Ha, 1994) studied and optimized the conditions (including DNA concentration, protoplast density, age of the suspension, and field strength used for electroporation) for electroporation transformation of tall fescue protoplasts using *GUS* transient expression assays. Kuai and Morris (1995) found that the age of the suspension, the stage of the growth cycle, the time length of cell wall digestion, and the osmolarity of the transformation medium all affected transient and stable *GUS* reporter gene expression in PEG-mediated protoplast transformation. Dalton *et al.* (1995) tested different hyg B selection schemes in PEG-mediated protoplast transformation and observed that continuous selection at a low concentration (50 mg l⁻¹) yielded the highest transformation frequency, and continuous selection at high level biased selection of transgenic plants with multiple transgene copies. The same group (Bettany *et al.*, 2002) reported the highest co-expression frequency (38%) of two co-transformed vectors when the molar gene ratio was 4:1. Spangenberg *et al.* (1995a) obtained transgenic plants by particle bombardment of embryogenic suspensions and hyg B selection. They observed a twofold improved efficiency in recovering resistance calli when the initial selection (hyg B, a step-up selection scheme from 30 up to 150 mg l⁻¹) was performed in liquid culture medium, compared to a continuous solid medium selection (150 mg l⁻¹). About 35% of the hyg B-resistant calli regenerated into plants. Kuai *et al.* (1999) recovered a transgenic plant

line of the *bar* gene by protoplast transformation and PPT selection (1.5–3 mg l), which showed resistance to PPT spray and was fertile. However, with limited number of seeds set by crossing with nontransgenic plants, they did not observe transmission of the *bar* gene to the T₁ progenies through pollen. Cho *et al.* (2000) adjusted concentrations of 2,4-D, BAP, and CuSO₄ in the culture medium and obtained regenerative tissues containing “multiple, light green, shoot-meristem-like structures” from mature caryopses (cv. Kentucky 31) cultured under dim-light conditions. They co-transformed the tissue with *hpt*, *bar*, and *GUS* transgenes by particle bombardment, and recovered 8 independent transgenic plant lines from hyg B selection (30–100 mg l⁻¹). Co-expression of two transgenes (*hpt* and *bar* or *GUS*) were 50–75%, and 25% transgenic plants had expression of all the three genes. Bai and Qu (2001b) reported transformation of two elite turf-type cultivars (Coronado and Virtue) by bombardment of embryogenic suspensions and hyg B (250 mg l⁻¹) or bialaphos (3–5 mg l⁻¹) selection. Dalton *et al.* (1998) employed silicon carbide “whiskers” method to transform suspensions and obtained 8 transgenic plants. Bettany *et al.* (2003) first reported *Agrobacterium* transformation of tall fescue. They infected suspensions with *Agrobacterium* strain LBA4404 harboring a “super-binary” vector pTOK233 and recovered two independent transgenic plant lines. Later on, more efficient *Agrobacterium*-mediated transformation was reported by three laboratories using 5–8 weeks of embryogenic calli induced from mature caryopses. Lee *et al.* (2004) found that a combination of strain EHA101 (pIG121Hm), 100 μM acetosyringone, and a 30-min vacuum treatment during co-cultivation yielded the best results: over 20% transformation frequency was achieved when hyg B selection was performed at 50 mg l⁻¹ level (cv. Kentucky 31). Wang and Ge (2005a) broke embryogenic calli into small pieces (cv. Jesup and Kentucky 31) and infected them with *Agrobacterium* strains LBA4404 or EHA105 harboring pTOK233 or a pCAMBIA binary vector, and selected the transgenics at 250 mg l⁻¹ hyg B. An average of 5.5% overall transformation efficiency (independent transgenic plant lines over the number of intact callus pieces infected) was achieved. No advantage of pTOK233 over pCAMBIA vectors was observed.

Fertile plants were obtained and Mendelian inheritance of transgenes was observed at T_1 generation by PCR analysis. Dong and Qu (2005) transformed calli of elite turf-type cultivars Matador and Coronado, and infected them with *Agrobacterium* strains LBA4404 or EHA105 containing binary vector pCAMBIA1301 with or without pTOK47, a vector similar to pTOK233. Approximately 34% of the calli infected were resistant to hyg B selection (250 mg l^{-1}), and 8% overall transformation frequency was achieved. They observed that a higher level of 2,4-D (5 mg l^{-1}) during callus culture and co-cultivation helped improve the transformation efficiency while inclusion of pTOK47 did not. In all the three reports, low transgene copy number in transgenic plants was observed. Recently, Cao *et al.* (2006) obtained highly regenerative callus lines from mature caryopses culture (cv. Triple A) on a modified N6 medium and found higher pH (6.2) enhanced both calli induction and plant regeneration. After co-cultivation with strain EHA105 (pCAMBIA1301), the calli were cultured on a nonselective preregeneration medium containing 400 mg l^{-1} L-cysteine for 7 days followed by regeneration on a nonselective medium. The selection pressure was imposed at the rooting medium (70 mg l^{-1} hyg B), and putative transgenic plants developed roots. In studies of transgene stability and inheritance in transgenic tall fescue plants, Bettany *et al.* (1998) investigated two transgenic plants in their GUS expression after vegetative propagation (tillering). The plants either had multiple *GUS* gene copies or the transgene had deletion or rearrangement. Considerable variations in GUS enzyme activity, among the tillers and from generation to generation, were observed mostly in the first four generations, and GUS expression seemed to be stabilized by the fifth generation. Southern and DNA methylation analysis could not identify obvious difference between the tillers that had various GUS activities. On the other hand, Z.Y. Wang *et al.* (2003a) studied *hph* and *GUS* transgene inheritance in transgenic plants obtained by particle bombardment through reciprocal crosses. Among over 40 T_1 plants from each cross, an 1:1 segregation ratio was observed by PCR analysis, indicating that both of the transgenes were inherited as a genetic locus, and the transgenes were transmitted by both egg cells

and pollen grains. Southern analysis showed the same hybridization pattern among T_0 , T_1 , and T_2 plants, suggesting a stable inheritance of the transgenes through sexual reproduction. To facilitate inheritance study, Z.Y. Wang *et al.* (2003b) developed a protocol for vernalization of transgenic tall fescue plants. In addition, the same group (Z.Y. Wang *et al.*, 2003c) investigated the field performance of transgenic tall fescue plants in comparison with nontransgenic, regenerated plants through tissue culture and nontransgenic, seed-derived plants. Although the T_0 transgenic and the tissue culture plants were inferior to the seed-derived nontransgenic plants in terms of height, tiller number, and seed yield, no major differences were observed among their progenies. In general, transgenic plants performed similarly to the tissue culture plants, and no major effect was observed from transgene introduction.

Kentucky Bluegrass transformation was first reported by Ha *et al.* (2001). The authors used an approach similar to what they did with tall fescue (Cho *et al.*, 2000) to obtain highly regenerative tissues from mature caryopses (cv. Kenblue) and co-bombarded the explants with three transgenes (*hpt*, *GUS*, and *gfp*) and the bombarded tissues were subjected to hyg B selection, first at 100 mg l^{-1} and later at 30 mg l^{-1} . It took quite a few months of subculture before the resistant, light-green tissues were observed. A transformation efficiency of 2.2% was achieved and 70% of the resistant tissues regenerated into plantlets. Co-expression frequency of two transgenes was 30–40%, and for all three genes was 20%. Gao *et al.* (2006) reported an efficient transformation protocol for Kentucky bluegrass using particle bombardment. The authors induced calli from immature embryos (breeding line DP-37-61), of which 90% were embryogenic. They achieved 22% transformation efficiency with the *hpt* transgene and hyg B (100 mg l^{-1}) selection, or 7.5% with the *bar* transgene and bialaphos selection (2 mg l^{-1}). The *bar* gene transgenic plants were resistant to herbicide BastaTM. The authors attributed their high transformation efficiency to a combination of the genotype and explant they employed, and the careful selection of the embryogenic callus lines used for the transformation experiments. *Agrobacterium* transformation of Kentucky bluegrass has been reported. Chai *et al.* (2003) found supplement of cupric sulfate enhanced induction

of embryogenic calli from mature caryopses (cv. Md). Embryogenic calli were infected with strain AGL1 (pDM805) and selection was carried out with bialaphos ($1.5\text{--}3\text{ mg l}^{-1}$). Four transgenic lines were obtained and the transgenic plants showed resistance to BastaTM spray.

Stable transformation of perennial ryegrass was first achieved with particle bombardment of a nonembryogenic suspension line, and hyg B resistance callus lines were obtained (Van Der Maas *et al.*, 1994). Spangenberg *et al.* (1995b) optimized conditions of bombardment of single-genotype derived embryogenic suspension lines (cv. Citadel) using a particle flow gun. They found that initial liquid selection and a stepwise increase of hyg B selection (from $50\text{--}200\text{ mg l}^{-1}$) had higher transformation efficiency with 26% bombarded plates yielded resistant calli, of which 23% regenerated. Wang *et al.* (1997) performed PEG-mediated protoplast transformation using a selection system containing the *nptII* gene and kanamycin/G418, which is more often used in dicot transformation. The transformed protoplasts were embedded in agarose with no nurse culture and first subjected to selection at 25 mg l^{-1} kanamycin, followed by selection at 25 and 40 mg l^{-1} G418, respectively. A transformation frequency of 5×10^{-6} was achieved, and 20 green plants were obtained. Fertile plants set seeds after crossing and the transgenes were inherited to T1 progenies. Folling *et al.* (1998) found that the nuclease activity released from protoplasts degraded DNA vectors and decreased transformation frequency. Raising the pH of the transformation buffer to 9 and performing transformation at 0°C reduced the nuclease activity and improved transformation frequency by nearly fivefold. Similar to what they did in tall fescue, Dalton *et al.* (1998) also described perennial ryegrass transformation using silicon carbide, and recovered a transgenic plant. The same group later found that the transformation efficiency of the particle inflow gun was “considerably higher”, and used the approach to transform the suspensions of an agronomically more important diploid cultivar (Dalton *et al.*, 1999). They employed liquid culture selection at the first 2–3 weeks at 50 mg l^{-1} hyg B and then solid culture selection at 75 mg l^{-1} of hyg B, and eventually recovered 6 transgenic plants. Altpeter *et al.* (2000) described a selection scheme using *nptII* gene and paromomycin (100 or 200 mg l^{-1})

after particle bombardment of calli induced from mature and immature embryos and immature inflorescences. Dozens of fertile transgenic plants were generated, and the transformation efficiency ranged from 3.7% to 11.4%. Recently two articles described high efficiency transformation of perennial ryegrass by the *Agrobacterium*-mediated approach. Bajaj *et al.* (2006) induced calli from the longitudinally sliced meristematic regions of seedlings. Among 250 lines, 6 highly regenerable callus lines were selected and maintained as plants *in vitro*, and the calli induced from the meristematic regions of these plant tillers were infected with *Agrobacterium* strain EHA101. Transformed calli were selected with hyg B at $94.8\text{ }\mu\text{M}$ (50 mg l^{-1}) for the first 2 weeks and $151.6\text{ }\mu\text{M}$ (80 mg l^{-1}) for the second round. About 7% transformation frequency was achieved and more than 1000 transgenic plants were obtained. Using a similar *Agrobacterium*-mediated transformation and selection scheme as they did in tall fescue, Cao *et al.* (2006) achieved 23.3% transformation efficiency for perennial ryegrass.

Creeping bentgrass transformation was first achieved by particle bombardment of embryogenic calli and the transgenic plants were identified by the GUS transgene expression without any selection (Zhong *et al.*, 1993). Hartman *et al.* (1994) introduced the *bar* gene into two cultivars of creeping bentgrass through bombardment of embryogenic suspensions, and recovered 55 transgenic plants resistant to herbicide Herbiace[®], suggesting they could be used in the golf greens to help solve the *Poa annua* weed problems. Lee *et al.* (1996) introduced the *bar* gene into protoplasts using either PEG treatment or electroporation, and obtained 153 transgenic plants resistant to Herbiace[®]. Xiao and Ha (1997) reported efficient recovery of *hph* transgenic plants using 200 mg l^{-1} hyg B selection after bombardment of suspensions. Asano *et al.* (1998) found that substitution of CaCl_2 with $\text{Ca}(\text{NO}_3)_2$ and elevated pH (9 to 10) in the buffer improved transient GUS activity in protoplast electroporation transformation, and used the altered buffer to recover *bar* transgenic plants. Dalton *et al.* (1998) obtained 6 transgenic plants from silicon carbide transformation of creeping bentgrass. *Agrobacterium*-mediated transformation of creeping bentgrass was first reported by Yu *et al.* (2000) in which the authors introduced a *gfp* gene and recovered the transgenic

plants by detecting the green fluorescence without any selection. Using *Agrobacterium*-mediated transformation and *bar* gene selection, Luo *et al.* (2004b) obtained a large number of transgenic plants (219 independent transformation events) with stable transformation frequency of 18–45%. The *bar* gene was stably expressed in T₁ plants and a Mendelian inheritance was observed among T₁ populations. About two-thirds of the transgenic plants had a single copy of the *bar* transgene. Han *et al.* (2005) reported *Agrobacterium* transformation of creeping bentgrass and *hyg B* selection. A novel *Agrobacterium*-mediated transformation of creeping bentgrass (cv. Penncross) was reported (Wang and Ge, 2005b) in which the nodes from stolons were cut into half and directly infected by *Agrobacterium*. Green shoots were produced from the infected nodes 4–5 weeks under *hyg B* selection in a medium containing 4.5 μ M kinetin and 0.2 μ M 2,4-D. The approach was efficient (6.3–11.3%) and transgenic plants can be quickly recovered. Moreover, this approach bypasses the callus induction and regeneration stages and may save a great deal of efforts in improving tissue culture responses, and has potential to be a way for genetic transformation of recalcitrant grass species. It would be interesting to see whether any transgenic plants obtained this way are chimeric and if not, histologically what kind of cells were transformed and formed the shoots. In other aspects, Fu *et al.* (2006) analyzed the integration sites of the transfer DNA (T-DNA) in transgenic creeping bentgrass and found that, like in other plants, the integration is a rather complicated process and may have diverse mechanisms, such as the microsimilarity-based illegitimate recombinations, and involvement of filler DNA, and/or T-DNA truncation. Fei and Nelson (2004) evaluated four transformation events of roundup-tolerant creeping bentgrass expressing the *cp4 epsps* gene, in fitness-related reproductive traits, such as heading date, anthesis duration, inflorescence length, number of florets per inflorescence, pollen size, and seed set capacity by open pollination. No significant differences were observed between the transgenic plants and the nontransgenic plants obtained through tissue culture.

Agrobacterium-mediated transformation of colonial bentgrass was reported by Chai *et al.* (2004). Embryogenic calli from mature caryopses

of cv. Tiger were induced on a MS medium containing 2 mg l⁻¹ 2,4-D, and infected with *Agrobacterium* strain LBA4404 (pTOK233) in the presence of 100 μ M acetocyringone. The infected calli were selected with *hyg B* first at 50 mg l⁻¹ and later at 70 mg l⁻¹, and the callus regeneration medium contained 50 mg l⁻¹ *hyg B*, and the plantlets were further selected at 20 mg l⁻¹ for rooting. After two cycles of selection, 81.2% of the *hyg B* resistant calli had strong *GUS* expression while roots of all *hyg B*-resistant plants and some leaves also showed *GUS* activity. Southern analysis of four randomly chosen *hyg B*-resistant plants showed integration of the *hpt* transgene in the plant genome.

Spangenberg *et al.* (1994) developed a red fescue protoplast culture system from fresh or cryopreserved suspensions using agarose beads, nurse culture, and regenerated plantlets. They employed the system and introduced the *bar* gene into red fescue by PEG treatment and recovered transgenic plants under selection at high concentration (50 mg l⁻¹) of PPT. The plants survived spray of herbicide BastaTM. Using the embryogenic suspensions, the same group (Spangenberg *et al.*, 1995a) later reported red fescue transformation by the biolistic method. Eighty-five percent of the resistant calli regenerated into plantlets. Cho *et al.* (2000) used an approach similar to what they did in tall fescue and Kentucky bluegrass as mentioned above, by generating highly regenerative green tissues and bombardment, and obtained transgenic red fescue plants with a stepwise increased selection of *hyg B* (30–100 mg l⁻¹). Altpeter and Xu (2000) bombarded embryogenic calli with an *nptII* gene construct and used 100 mg l⁻¹ paromomycin for selection. Between 3% and 5% of the bombarded calli of red fescue produced transgenic plants. No transformation of other fine fescues was reported.

Among the warm-season grasses, bermudagrass transformation was first reported in the triploid, interspecific hybrid (*C. dactylon* \times *C. transvaalensis*, cv. TifEagle). Zhang *et al.* (2003) induced embryogenic calli from stolons and developed suspensions from them. The suspensions were bombarded with a vector containing the *hpt* gene. Seventy-five transgenic plants were obtained under selection of 200 mg l⁻¹ *hyg B*. The integration and expression of the transgene were stable during vegetative propagation. Goldman *et al.* (2004a)

transformed embryogenic calli of TifEagle with the herbicide-resistant *bar* gene, and recovered 89 transgenic plants from at least 9 transformation events using selection of 5–15 mg l⁻¹ PPT. The transgenic plants were resistant to herbicide Liberty[®]. Flow cytometry revealed that most of the plants (82/89) were hexaploid, which often showed significant variation in leaf length and width from the parent cultivar. However, no detectable difference was observed in amplified fragment length polymorphism (AFLP) analysis between the hexaploid transgenic plants and the triploid parent cultivar plants. Hu *et al.* (2005) reported *Agrobacterium*-mediated transformation of TifEagle with the *hpt* gene and hyg B selection. A total of 24 independent transgenic plant lines were obtained. Since the vector used for transformation also contained the *bar* gene, plants expressing the *bar* gene displayed resistance to herbicide Liberty[®]. Li and Qu (2004) developed highly regenerable callus lines from tetraploid common bermudagrass (*C. dactylon*) cv. J1224, and recovered transgenic plants from four independent transformation events by particle bombardment and hyg B selection (200 mg l⁻¹ at callus level and 100 mg l⁻¹ at regeneration stage). Because of the *bar* and *GUS* genes in the vector used for co-transformation, one event had *GUS* activity and three events were resistant to Liberty[®]. The group later reported *Agrobacterium* transformation of the same cultivar using both callus lines and suspension cells, and hyg B selection (Li *et al.*, 2005). Flow cytometry analysis indicated that the ploidy level of the transgenic plants was not altered. Attempts to use *bar* gene selection resulted in transgenic calli but no plants were recovered. Similar to the approach used in creeping bentgrass, successful transformation through direct node infection by *Agrobacterium* was reported in triploid, hybrid bermudagrass (cv. TifEagle, Wang and Ge, 2005b).

Japanese lawngrass transformation was first reported using direct gene transfer to protoplasts mediated by PEG (Inokuma *et al.*, 1998). The authors found that 400 mg l⁻¹ hyg B was a proper level for the selection of resistant cell colonies. The selection seemed to be quite efficient and about 400 transgenic plantlets were recovered without selection at the regeneration stage. Toyama *et al.* (2003) first reported *Agrobacterium* transformation of the Japanese lawngrass. They observed that removal

of 2,4-D and CaCl₂ from the infection medium, and extension of the co-cultivation period to 9 days enhanced transient *GUS* reporter gene expression, and thus used these conditions to perform transformation. Four bialaphos-resistant plants were regenerated per 700 mg calli after a step-up selection at callus and shoot levels (0.5–5 mg l⁻¹) and 10 mg l⁻¹ bialaphos at rooting medium. Ge *et al.* (2006) again, successfully applied their “node-infection-by-*Agrobacterium*” approach to Japanese lawngrass and obtained shoots resistant to hyg B selection (75 mg l⁻¹) in 4–5 weeks. Approximately 50% of the resistant plants were transgenic, and a transformation frequency of 6.8% was achieved.

Genetic transformation of buffalograss has been reported (Fei *et al.*, 2005). Embryogenic calli induced from female immature inflorescences of cv. 91–118 were subcultured for 15 months to obtain soft, friable, and highly regenerable calli, which were bombarded with gold particles of 0.75 mm in diameter. A delay of selection (7 or 28 days) yielded about 2% of calli resistant to glyphosate using a vector containing two *cp4 epsps* gene constructs. In total, 77 pieces (2.2%) of calli were resistant to glyphosate (1 or 2 mM) selection and transferred to regeneration medium containing 0.1 mM glyphosate. Three green shoots developed roots in the selection-rooting medium (0.05 mM glyphosate). Trait RUR Lateral Flow Test strips revealed the resistant plantlets had CP4 EPSPS enzyme activity.

Genetic transformation of centipedegrass was recently achieved (Hanna, personal communication). No transformation of St. Augustinegrass or seashore paspalum was reported. However, Lee and Berg (1999) had a patent (US patent 5948956) on St. Augustinegrass transformation using bombardment of node segments and direct selection of the regenerated plantlets.

2.3 Useful Genes Used in Turfgrass Transformation and Their Effects

Appreciable progress in trait modifications using transgenic technologies in a variety of turfgrass species demonstrates the great potential of genetic engineering in plant breeding, and suggests ways for genetic improvement of turfgrasses at a much accelerated pace than before (Lee, 1996;

Chai and Sticklen, 1998; Wang *et al.*, 2001; Wang and Ge, 2006). Turf varieties with desired traits such as disease, insect, and herbicide resistance and environmental stress tolerance can be expected in the very near future. The use of genetically modified turf varieties on a large scale could benefit the turfgrass industry, lawn owners, and the environment. For example, new genes can be introduced into turf that confer traits such as drought and stress tolerance that will reduce water usage, pest resistance that will reduce pesticide applications, phyto-remediation capability and aluminum tolerance that will improve environmental qualities. So far, a large number of useful genes have been introduced into various turf species to produce transgenic plants with enhanced agronomic traits.

2.3.1 Genes conferring tolerance to biotic stress in turfgrass

Most plants, during their life cycle, frequently encounter biotic and abiotic environmental stresses that adversely affect their growth, development, or productivity. Biotic stresses are imposed to plants either by infection with bacteria, fungi, viruses, insects, and nematodes, or by competition with weeds or other undesirable plant species. Resistance to biotic stress is one of the most important targets in the improvement of turfgrass. Although knowledge of the molecular mechanism involved in biotic stress tolerance of turfgrass is limited, and studies in this area lag far behind other major crop species, information from model species, such as *Arabidopsis* and rice whose genomes have been recently sequenced, and other grass species, provides insights into the complexities of the processes as well as candidate genes to be used in genetic engineering of turfgrass plants with durable resistance to biotic stress.

2.3.1.1 Fungal resistance

Turfgrass species are highly susceptible to a wide range of destructive fungal pathogens and require extensive application of fungicides to maintain turf quality. This not only adds to operational costs, but also raises environmental concerns. Plants have evolved mechanisms to

protect themselves from fungal attacks, including coordinated activation and expression of a number of genes encoding pathogenesis-related (PR) proteins, or the expression of specific resistance (R) genes for certain pathogens. In addition, genes identified from sources other than plant kingdom also have been demonstrated to confer disease resistance in plants. With the rapid development of transgenic techniques for use in different turfgrass species, a great number of different disease resistance mechanisms have been genetically engineered into turfgrass species to strengthen the host resistance to fungal attacks and demonstrated to be quite effective, pointing to the great potential of exploiting more in this path for use in practice.

Chitinase and glucanase Chitinase, identified in a wide variety of plants, is one of the most representative pathogenesis response-related proteins (PR3) that are induced strongly during fungal infection, treatment of plant tissues with fungal cell wall extracts, or wounding (Collinge *et al.*, 1993; Graham and Sticklen, 1994). Plant chitinases can attack pathogens directly by degrading chitin (a fungal cell wall component) to confer disease resistance, or by binding to the chitin of the fungal cell wall to interfere with fungal growth because of the affinity of chitin-binding proteins to nascent chitin, which leads to severe morphological changes in fungi (Nielsen *et al.*, 1997; Theis and Stahl, 2004). Chitinases are monomers of 25–35 kDa, found as acidic or basic forms, and consist of a putative chitin binding domain as well as a catalytic domain (Shinshi *et al.*, 1990). β -1,3-glucan is a major component of fungal cell walls. Plants have evolved to have β -1,3-glucanases (PR2) as one of the major PR proteins in their defense systems (De Lucca *et al.*, 2005). β -1,3-glucanases are believed to be able to directly digest the β -1,3-glucans of fungal cell walls, resulting in cell lysis, and/or release of bioactive cell wall fragments as elicitors for inducing plant defense reactions (Leubner-Metzger and Meins, 1999). Both chitinase and β -1,3-glucanase have been introduced into turfgrass aiming at engineering enhanced fungal resistance. Chai *et al.* (2002) transferred the elm chitinase gene (*hs2*) to creeping bentgrass, a cool-season grass mainly used in golf greens.

Creeping bentgrass is susceptible to several fungal diseases, especially *Rhizoctonia solani* (Kuhn), a basidiomycete fungus and the causal agent of brown patch disease, and *Sclerotinia homoeocarpa*, which causes dollar spot disease. Compared to the untransformed plants, two transgenic lines out of five showed improved resistance to brown patch disease. Interestingly, the same group also demonstrated the prevention of fungal diseases in transgenic creeping bentgrass expressing herbicide-resistant gene, *bar*, after spraying of transgenic plants with bialaphos and glufosinate (Liu *et al.*, 1998). This observation was confirmed in separate studies when both a rice chitinase *RCH 10* gene and an alfalfa glucanase *AGLU1* gene were co-transferred with a *bar* gene into creeping bentgrass. Although the transgenic plants themselves did not exhibit resistance to these two fungal pathogens, they became resistant to both dollar spot and brown patch diseases when the herbicide glufosinate was sprayed before the fungal inoculation (Y. Wang *et al.*, 2003a, b). Chitinase also has been introduced into Italian ryegrass (*Lolium multiflorum* Lam.), one of the most important temperate pasture grasses, and sown for forage and turf, to improve plant resistance to crown rust (*Puccinia coronata*), the most serious foliar fungal disease (Takahashi *et al.*, 2005). An *RCC2* gene encoding rice chitinase (*Cht-2*) (Nishizawa *et al.*, 1993) was used to transform Italian ryegrass. Bioassay of detached leaves indicated increased resistance to crown rust in transgenic plants, which exhibited higher chitinase activity than a nontransgenic plant (Takahashi *et al.*, 2005). A recent study in introducing the alfalfa glucanase *AGLU1* gene into tall fescue (*F. arundinacea* Schreb.), a cool-season turf and forage grass species of great economic importance, has resulted in transgenic plants with enhanced resistance to various fungal diseases (Dong *et al.*, 2007). Among the 12 tall fescue plants containing the *AGLU1* gene, two were resistant to brown patch (*R. solani*), and three were highly resistant to another fungal disease, gray leaf spot, caused by an ascomycete fungus of *Magnaporthe grisea* (T.T. Hebert) Yaegashi and Udagawa.

Thaumatococcus-like proteins (TLPs) Group PR5 of the PR proteins are known as thaumatococcus-like proteins (TLPs) because of their homology to

the sweet-tasting thaumatococcus from *Thaumatococcus daniellii* (Edens *et al.*, 1982). PR5 proteins have been found to have antifungal activity, presumably by disrupting fungal plasma membrane (Vigers *et al.*, 1992). A rice thaumatococcus-like protein gene, *tlpd34*, under the control of maize ubiquitin (*ubi1*) promoter was introduced into creeping bentgrass and the transgenic plants expressing TLPD34 showed improved resistance to dollar spot in the field tests although the same transgenic lines showed no improvement against brown patch under greenhouse conditions (Fu *et al.*, 2005). In a separate study, an *Arabidopsis thaliana* (L.) Henyeh gene encoding for PR5K, a receptor protein kinase that has an extracellular domain with similarity to the PR5 proteins, was also placed under the control of maize *ubi1* promoter, and introduced into creeping bentgrass. Four of the eight transgenic lines expressing PR5K exhibited delays in development of dollar spot disease symptoms by 29–45 days, relative to the control plants after inoculation (Guo *et al.*, 2003).

Plant resistance (R) genes Plant R genes express in response to the invasion of certain pathogens. They consist of common motifs such as a nucleotide binding site (NBS), leucine-rich repeats (LRRs), kinase, coiled-coil domain (CC), Toll/interleukin-1-receptor (TIR), and transmembrane domain (Hammond-Kosack and Jones, 1997). The R gene products recognize corresponding avirulence gene products (elicitor) from the pathogen, which trigger the cascade of plant defense responses, such as hypersensitive response or programmed cell death, and consequently slow down or completely stop the growth of the pathogen (Dangl *et al.*, 1996; Pennell and Lamb, 1997). *Pi9*, an unusual rice blast R gene that exhibited high resistance to all the rice blast-causing races of *M. grisea* tested so far (Qu *et al.*, 2006), was recently introduced into tall fescue as a genomic DNA fragment with its own gene expression regulatory element and transcriptional terminator. Preliminary results obtained from the transformed plant showed that *Pi9* conferred a high level of resistance to the turfgrass isolates of *Magnaporthe grisea* (Dong *et al.*, 2007).

Ribosome-inactivating proteins (RIPs) RIPs are toxic N-glycosidases that cleave a highly conserved sequence of the 28S rRNA (Endo and Wool, 1982; Theis and Stahl, 2004). RIPs identified in many plant species are believed to function as defense proteins (Stirpe *et al.*, 1992; Barbieri *et al.*, 1993; Nielsen and Boston, 2001). Three types of RIPs from pokeweed (*Phytolacca americana*), referred to as pokeweed antiviral proteins (PAPs), PAP-Y, PAP-C, and PAPII (Irvin *et al.*, 1980; Irvin, 1983) were used to transform creeping bentgrass under the control of maize *ubil* promoter. Transgenic plants produced exhibited different levels of PAP expression, some of which displayed resistance to dollar spot disease (*S. homoeocarpa*) albeit toxic effect of highly expressed PAPs on host plants (Dai *et al.*, 2003).

Lysozymes Lysozymes exist widely in microorganisms and animals, and are generally considered to be antibacterial because of their 1,4- β -N-acetylmuramidase activity against peptidoglycan in bacterial cells (Jolles and Jolles, 1984). Some lysozymes can hydrolyze chitin and thus also have antifungal activities. Antifungal activity of T4 lysozyme was first observed after abolishing the muramidase activity by heat treatment, and the C-terminal of the enzyme was considered to confer this “membrane-disturbing” activity (Düring *et al.*, 1999) confer resistance to fungal attack in transgenic rice, where over 80% of the transgenic plants expressing T4 lysozyme were resistant to four isolates of the rice blast pathogen *M. grisea* (Tian *et al.*, 2002). This demonstrates the great potential of T4 lysozyme for use in plants in defending fungal attacks. T4LYS, the T4 phage lysozyme gene driven by maize *Ubi1* promoter was introduced into tall fescue to test its utility in conferring disease resistance to transgenic plants (Dong *et al.*, 2008). Among the 14 transgenic plants obtained, seven showed highly significant resistance to gray leaf spot (*M. grisea*). Moreover, three of these plants were also resistant to brown patch disease (*R. solani*). The results demonstrated the potential to introduce T4 lysozyme gene into plants for fungal disease resistance.

Small antimicrobial peptides Fungi, insects, animals, and humans all possess genes encoding

antimicrobial proteins or peptides. Many antimicrobial proteins/peptides have been identified and some have been introduced into plants for enhanced disease resistance. Small antimicrobial peptides also can be engineered into plants for disease resistance. Typically, these antimicrobial peptides permeabilize the cell membrane or cause osmotic shock to the pathogens (Nissen-Meyer and Nes, 1997). Dermaseptins are small antimicrobial peptides originally isolated from frog skin. Dermaseptins and their truncated analogs were cytolytic to bacteria, yeast, filamentous fungi, and protozoa (Mor and Nicolas, 1994). Immunofluorescence, electron microscopic, and electrophysiological studies indicated that the interactions between the peptide and the lipid bilayer of cells caused changes in membrane functions, which resulted in the imbalance of the osmotic pressure and cell death (Pouny *et al.*, 1992). A derivative of a dermaseptin B gene was reported to confer resistance to fungal pathogens from *Alternaria*, *Cercospora*, *Fusarium*, *Phytophthora*, *Pythium*, *Rhizoctonia*, and *Verticillium* genera in transgenic potato (Osusky *et al.*, 2005). Recently, a truncated dermaseptin SI gene encoding a peptide of 18 AA residues (ALWKTMLKKLGTMAL-HAG), which was demonstrated to exhibit active antimicrobial activity (Mor and Nicolas, 1994), was introduced into tall fescue under the control of rice *rubi3* gene promoter (Dong *et al.*, 2007). The two transgenic plants expressing the truncated dermaseptin SI gene grew normally and displayed good resistance to gray leaf spot (*M. grisea*). One of them tested was also resistant to brown patch disease (*R. solani*). This preliminary result, together with the results reported in potato (Osusky *et al.*, 2005), suggests the potential of using dermaseptins to render resistance to a wide spectrum of fungal pathogens in turfgrass.

2.3.1.2 Virus resistance

Virus disease is another biotic stress that has big impact on certain turfgrass species. Plant-derived virus resistance genes are often unavailable. Pathogen-derived resistance (PDR) (Sanford and Johnston, 1985) mediated by transgene (virus coat protein genes, replicase genes, or movement protein genes) products, either the proteins (protein-mediated) or the transcripts

(RNA-mediated), have been demonstrated to be very effective in fighting against viruses in plants (Baulcombe, 2005). RNA-mediated virus resistance may operate by targeted degradation of the transgene and homologous virus RNA, resulting in post-transcriptional gene silencing (PTGS) along with inhibition of virus RNA replication. This strategy was used in perennial ryegrass (*Lolium perenne* L.), the most important grass sown in areas with a temperate climate, to genetically engineer resistance to a common perennial ryegrass pathogen, ryegrass mosaic virus (RgMV), which can tremendously reduce plant yield and persistence (Xu *et al.*, 2001). RgMV belongs to the family Potyviridae, genus *Rymovirus*, and is a cytoplasmically replicating virus with a monocistronic ssRNA genome. An untranslatable RgMV coat protein gene (*RgMV-CP*) driven by the rice *Act1* promoter was introduced into perennial ryegrass. Primary transgenic plants and their sexual progeny exhibited resistance against high-dose virion inocula of different RgMC strains over a 9-month monitoring period after inoculation.

2.3.2 Genes conferring tolerance to abiotic stress in turfgrass

Abiotic stresses arise from an unfavorable physical or chemical environment surrounding the plant, such as water deficit or flooding, high or low temperatures, excessive soil salinity, inadequate mineral nutrients, or presence of pollutants, such as heavy metals in the soil and chemicals, such as herbicides. Many factors interact to determine how plants respond to environmental stresses, including the features of the plants (genotype, developmental stages, and organ or tissue identity), the way a stress is imposed (duration, severity, and frequency) and the additive or synergistic effect of multiple stresses (Bray *et al.*, 2000). Although none of the mechanisms by which higher plants perceive abiotic stresses have been elucidated, tremendous progress in understanding plant responses to stress through different mechanisms has been made (Bohnert *et al.*, 1995; Shinozaki and Yamaguchi-Shinozaki, 1999; Bray *et al.*, 2000; Shinozaki *et al.*, 2003). This knowledge allows designing molecular strategies to genetically modify plants of various species,

including turfgrass, for enhanced abiotic tolerance, leading to improved agricultural production.

2.3.2.1 Drought and salt tolerance

Drought and salinity are the most important osmotic stresses affecting plant growth and productivity. Plants respond to water deficit and adapt to drought and salinity conditions by changes in metabolism and development that can often be attributed to altered patterns of gene expression. Many higher plants have evolved mechanisms such as the accumulation of osmoprotectants including amino acids, ammonium compounds, and polyols/sugars to protect themselves from drought and salt stress conditions. This provides tolerance to the cells under stress by stabilizing the quaternary structure of the complex proteins and adjusting the osmotic potential in their cytoplasm to maintain water content. Recent progress has been made in analyzing the complex cascades of gene expression in drought and cold stress responses, especially in identifying specificity and cross talk in stress signaling (Shinozaki *et al.*, 2003; Siobhan *et al.*, 2003).

Several of the stress-induced genes are regulated by ABA, a plant hormone that is increased through *de novo* synthesis in response to water deficit and low temperature. ABA plays a role in several responses to water stress, most notably stomatal closure and induction of gene expression (Crozier *et al.*, 2000; Trewavas, 2000). This suggests the great potential of manipulating ABA levels in plants by enhanced expression of key regulatory genes in ABA biosynthesis for mitigating plant tolerance to water stress, and has been demonstrated in transgenic *Arabidopsis* (Iuchi *et al.*, 2001) and tobacco (Qin and Zeevaart, 2002) plants overexpressing a gene for 9-cis-epoxycarotenoid dioxygenase (Qin and Zeevaart, 1999) that catalyzes the cleavage of 9-cis-epoxycarotenoids, the first committed and presumably the limiting step of ABA biosynthesis. Recently, *VuNCED1*, a 9-cis-epoxycarotenoid dioxygenase gene cloned from cowpea (Iuchi *et al.*, 2000) and placed under the control of the CaMV 35S promoter was introduced into creeping bentgrass (Aswath *et al.*, 2005). Challenge studies performed with transgenic plants by exposure to water stress (up to 75%) and salt stress (up to 10 dSm⁻¹) for

10 weeks, revealed that more than 50% of the transgenic plants could survive drought and NaCl stress whereas wild type was not. ABA levels were measured under drought and normal conditions; endogenous ABA was dramatically increased by drought and NaCl stress in transgenic plants.

The detrimental effects of salt on plants are a consequence of both a water deficit resulting in osmotic stress and the effects of excess sodium ions on key biochemical processes. To tolerate high levels of salts, plants should be able to use ions for osmotic adjustment and to internally distribute these ions to keep sodium away from the cytosol. Vacuolar Na^+/H^+ antiports, the prevalent membrane proteins, found in animals, yeasts, bacteria, and plants (Fukuda *et al.*, 1999), play important roles in this process. They function to pump Na^+ from cytoplasm into vacuole, to maintain a higher K^+/Na^+ ratio in the cytoplasm than that in vacuoles, protecting cell from sodium toxicity (Fukuda *et al.*, 1999). In addition, the vacuolar proton pumps, such as the vacuolar H^+ -pyrophosphatase, also should increase the sequestration of ions in the vacuole by increasing the availability of protons. Although salt tolerance is a complex trait that seems to involve a large number of salt-responsive genes (Zhu, 2000), the overexpression of a single gene, such as the vacuolar Na^+/H^+ antiport gene (Apse *et al.*, 1999; Zhang and Blumwald, 2001; Zhang *et al.*, 2001; Ohta *et al.*, 2002; Fukuda *et al.*, 2004) or the H^+ -pyrophosphatase gene (Gaxiola *et al.*, 2001; Park *et al.*, 2005), has been shown to improve plant tolerance to salt, and in some cases, to drought in transgenic *Arabidopsis*, tomato, and rice plants. A rice Na^+/H^+ antiport gene, *OsNHX1* driven by the CaMV 35S promoter has been introduced into perennial ryegrass (*L. perenne* L.) (Wu *et al.*, 2005). The resultant transgenic ryegrass had better salt tolerance. After stress treatment for 10 weeks with 350 mmol l^{-1} NaCl, transgenic plants survived, while wild-type plants did not. The leaves of transgenic plants accumulated higher concentrations of Na^+ , K^+ , and proline than those of the control plants.

2.3.2.2 Freezing and cold tolerance

Fructans are polyfructose molecules produced from the polymerization of sucrose that accu-

mulate in plants in addition to or instead of starch (Hendry, 1993). Fructans are particularly widespread in the grasses and predominantly stored as highly accessible, nonstructural carbohydrates in the vacuole where they are synthesized (Chatterton *et al.*, 1989; Hendry, 1993). Fructan not only plays an important role in assimilate partitioning (Pollock and Cairns, 1991; Schnyder, 1993), but also has been associated with improved tolerance to cold and drought through osmoregulation (Pontis, 1989; Pollock and Cairns, 1991; Hendry, 1993; Ebskamp *et al.*, 1994; Pilon-Smits *et al.*, 1995; Konstantinova *et al.*, 2002). The *sacB* gene for *Bacillus subtilis* levansucrase, one of the enzymes involved in the synthesis of high-molecular-weight bacterium fructan (levan) was placed under the control of the maize *ubi1* promoter, or the double CaMV 35S promoter and introduced into Italian ryegrass (*Lolium multiflorum* Lam.) (Ye *et al.*, 2001). In order to direct the expressed levansucrase to the vacuole (Ebskamp *et al.*, 1994), the *sacB* coding sequence was fused to the vacuolar targeting signal sequence from the yeast carboxypeptidase Y (*cpy*) or sweet potato preprosporamin (*spor*) genes (Hattori *et al.*, 1985; Valls *et al.*, 1987). Transgenic plants expressing the chimeric *sacB* gene accumulated low levels of bacterial levan and displayed distorted native grass fructan synthesis pattern and slowed growth with the onset of the reproductive phase. It is unclear how this was related to the response of transgenic plants to environmental stresses. In a separate study, transgenic perennial ryegrass (*Lolium perenne*) plants were produced that overexpressed the CaMV 35S promoter-driven wheat fructosyltransferase genes, *wft1* and *wft2*, which encode sucrose-fructan 6-fructosyltransferase (6-SFT) and sucrose-sucrose 1-fructosyltransferase (1-SST) (Kawakami and Yoshida, 2002), respectively. Significant increases in fructan content and freezing tolerance on a cellular level were detected in the transgenic perennial ryegrass plants (Hisano *et al.*, 2004).

Cytokinins, a class of phytohormones, play an important role in the processes of plant development. They have pleiotropic effects on plants when applied exogenously, including shoot initiation from callus cultures, promotion of axillary bud growth, directed transport of nutrients, stimulation of pigment synthesis, inhibition of root growth, and delay of senescence (Medford

et al., 1989). *ipt*, the *A. tumefaciens* cytokinin biosynthetic gene coding for the enzyme isopen-tenyl transferase involved in the rate-limiting step in cytokinin biosynthesis (Akiyoshi *et al.*, 1983), and has been transferred into plants to induce additional cytokinin production as well as a number of modifications in morphology and plant development (Li *et al.*, 1992; Hewelt *et al.*, 1994; Faiss *et al.*, 1997; Rupp *et al.*, 1999), some of which indirectly impacted on stress tolerance (Smigocki *et al.*, 1993; Li *et al.*, 2004). The *A. tumefaciens ipt* gene driven by maize *ubil* promoter was introduced into *F. arundinacea*, a cool season tall fescue turfgrass. Transgenic plants expressing exogenous *ipt* gene showed enhanced tillering ability, higher chlorophyll a and b levels, a longer stay-green period under low-temperature conditions and consequently, greatly improved cold tolerance (Hu *et al.*, 2005).

2.3.2.3 Transcription factors for use in abiotic stress tolerance

Abiotic stress-inducible transcription factors are capable of activating the expression of multiple downstream genes involved in protection against environmental stresses, thus leading to a wide-arrayed altered response. The transcription factor of the C-repeat/dehydration-responsive-element (C/DRE) pathway, DREB1A/CBF3 specifically interacts with the dehydration responsive element (DRE/CRT) of promoters of the responsive genes. Overexpression of *DREB1A* in transgenic plants of various species enhanced tolerance to different abiotic stresses with concomitant expression of target genes (Kasuga *et al.*, 1999, 2004; Jaglo *et al.*, 2001; Hsieh *et al.*, 2002a, b; Oh *et al.*, 2005). These results demonstrate the great potential of transgenic expression of regulatory genes as a more effective approach for enhancing plant stress tolerance. A DREB1A transcription factor ortholog BCBF3 isolated from wild barley and under the control of the stress-inducible barley *HVA1* promoter was introduced into bahiagrass (*Paspalum notatum* Flugge), an important warm season perennial grass to evaluate the effects of stress-inducible transgene expression on the response of transgenic plants to abiotic stress, and demonstrated to confer enhanced freezing and drought tolerance (James *et al.*, 2004).

2.3.3 Genes conferring tolerance to herbicides in turfgrasses

Weeds or other undesirable plant species (including turf species themselves) greatly impact turf quality for a given turfgrass species and may be considered to represent another type of biotic stresses. The use of herbicides to reduce loss in agricultural production due to weeds has become an integrate part of modern agriculture. The application of herbicides for controlling weeds in turfgrass calls for turf varieties with tolerance to different herbicides. Herbicide resistance in turfgrass through genetic engineering provides a very effective tool in golf course management and lawn maintenance.

2.3.3.1 Resistance to PPT, bialaphos, or glufosinate herbicide

Bialaphos herbicide is a tripeptide antibiotic produced by *S. hygroscopicus*, an organism that produces the tripeptide bialaphos as a secondary metabolite. It consists of two L-alanine residues and PPT, an analog of L-glutamic acid, which is an inhibitor of glutamine synthetase (GS). GS plays a central role in the assimilation of ammonia and in the regulation of nitrogen metabolism in plants. It is the only enzyme in plants that can detoxify ammonia released by nitrate reduction, amino acid degradation, and photorespiration. Inhibition of GS by PPT causes rapid accumulation of ammonia, which leads to death of the plant cell (De Block *et al.*, 1987). While PPT is an inhibitor of glutamine synthetase in both plants and bacteria, the intact tripeptide has little or no inhibitory activity *in vitro*. In both bacteria and plants, intracellular peptidases remove the alanine residues and release active PPT. The *bar* gene originally cloned from *S. hygroscopicus* is involved in the bialaphos biosynthesis pathway. It encodes a modifying enzyme, phosphinothricin acetyltransferase (PAT) that acetylates the free NH₂ group of PPT and thereby prevents autotoxicity in the producing organism (Thompson *et al.*, 1987). Since its first introduction into plants as a selectable marker in plant transgenic research (De Block *et al.*, 1987), it has been widely used in various plant species, including a number of turfgrass species (Wang

et al., 1992; Hartman *et al.*, 1994; Spangenberg *et al.*, 1994; Lee, 1996; Asano *et al.*, 1998; Liu *et al.*, 1998; Yu *et al.*, 2000; Y. Wang *et al.*, 2003a, b; Luo *et al.*, 2004b). A commercial creeping bentgrass cultivar that has been genetically engineered for glufosinate resistance and male sterility is currently under field trial (Luo *et al.*, 2004a, b, 2005).

2.3.3.2 Resistance to glyphosate herbicide

Glyphosate herbicide (marketed under the trade name Roundup) inhibits 5-enol-pyruvylshikimate-3-phosphate synthase (EPSPS) within the aromatic amino acid biosynthetic pathway. Disruption of this pathway not only creates a deficiency in protein synthetic precursors, but also affects many other plant cell components that are derived from intermediates and derivatives of this pathway (e.g., auxins, lignans, flavonoids, anthocyanins, and quinones). Therefore, a crop plant must be engineered with a resistant enzyme to maintain flux through this pathway for uninhibited growth and development. A naturally occurring form of EPSPS from *Agrobacterium* sp. strain CP4 provides tolerance to high concentrations of glyphosate. Transgenic expression of CP4 EPSPS within glyphosate-tolerant Roundup Ready[®] soybean, cotton, and canola provided the appropriate support to the aromatic amino acid biosynthetic pathway without negative impact on yield, compositional qualities, and nutritional value of the harvested product. The *Agrobacterium* CP4 EPSPS also has been genetically engineered into creeping bentgrass (*A. stolonifera* syn. *A. palustris*) to create Roundup-resistant transgenic lines that are currently in the process of applying for the United States Department of Agriculture (USDA) deregulation (Gardner *et al.*, 2003, 2004; Fei and Nelson, 2004).

2.3.3.3 Conversion of proherbicide to herbicide for selective elimination of undesirable plants

The *E. coli argE* gene encodes *N*-acetylornithinase in the *E. coli* arginine biosynthetic pathway, which removes the acetyl group from *N*²-acetylornithine and produces acetate and ornithine (Meinell

et al., 1992). The enzyme can also de-acetylate *N*-acetyl-PPT, a nontoxic compound, to produce PPT (Kriete *et al.*, 1996). This property was recently used in turfgrass to develop a strategy to eliminate undesirable plants in golf course management. Perennial ryegrass is widely used for winter overseeding of dormant bermudagrass on golf courses and sports fields in southeastern United States to provide green color and improved playability. Late spring and summer persistence of perennial ryegrass may decrease the quality of the bermudagrass turf and reduce its winter hardiness. To solve this problem, the *E. coli argE* gene under the control of maize *ubi1* promoter was introduced into perennial ryegrass and transgenic plants expressing the *argE* transgene were selectively controlled upon application of the nontoxic proherbicide, *N*-acetyl-PPT. The nontransgenic bermudagrass plants were unaffected by the treatment (Chen *et al.*, 2005). This approach provides a means to selectively remove a group of transgenic plants without affecting other plants growing with them.

2.3.4 Modification of other important traits in turfgrasses

2.3.4.1 Modification of senescence

Senescence-associated gene promoters, whose functional values have been demonstrated in dicot genetic manipulation (Gan and Amasino, 1997), are of considerable interest in grasses because of their probable involvement in economically important traits such as productivity (Thomas and Howarth, 2000), sward color (Thorogood, 1996), and responses to elevated CO₂ (Ludewig and Sonnewald, 2000). The 5' flanking sequence of a maize *SEE1* gene encoding cysteine protease was used to drive the *A. tumefaciens* cytokinin biosynthesis gene, *ipt*, in ryegrass (*L. multiflorum* Lam.). Transgenic analysis demonstrated that the *SEE1* flanking sequence functioned as a senescence-enhanced promoter in ryegrass. The *ipt* transgene was detected in 28 regenerants from five independent transformation events, and the leaves of transgenic plants displayed a stay-green phenotype. Some lines developed spontaneous lesions (Li *et al.*, 2004).

2.3.4.2 Floral inhibition

Flowering in plants is controlled by both environmental (primarily temperature and light) and genetic factors. The genetic factors include genes encoding transcriptional activators and repressors, such as MADS box genes, zinc-finger transcription factors, AP2-domain genes, MYB-domain genes, and also RNA-binding proteins, polycomb-group genes, starch metabolism related proteins, photoreceptors, circadian-clock controlling proteins, GA biosynthesizing enzymes, GA signaling repressors, etc. (reviewed in Levy and Dean, 1998; Simpson *et al.*, 1999). The genes that control the transition from vegetative to reproductive growth called floral meristem identity genes, act either by repressing or promoting flowering. For example, *TERMINAL FLOWER1* (*TFL1*), a floral meristem identity gene, identified in *Arabidopsis* has been demonstrated to specify an indeterminate identity of inflorescence meristems and extend plant vegetative phase. *Arabidopsis* plants overexpressing *TFL1* flower late and produce more secondary shoots (Ratcliffe *et al.*, 1998). Similar functions have been demonstrated in its homolog, *LpTFL1* isolated from perennial ryegrass (*L. perenne* L.). Expression of *LpTFL1* in *Arabidopsis* gave a remarkably strong phenotype with a dramatic delay in flowering (some nonflowering) and extended lateral branching (Jensen *et al.*, 2001).

In turfgrass, the stems that start to emerge during the growth season suppress the formation of new shoots and affect the quality, density, and persistence of the sward. Therefore, prolonged vegetative growth phase through delay of flowering is of major interest in genetic improvement of turfgrass. To manipulate the transition to flowering in turfgrass, the strong floral repressor, *LpTFL1* gene was introduced into red fescue (*F. rubra* L.), a commercially important cool-season turfgrass. Expression of *LpTFL1* with the constitutive maize *ub1* promoter represses flowering in red fescue, and the flowering repression phenotype correlates well with the level of *LpTFL* expression. Transgenic lines showing low to intermediate expression of *LpTFL1* flowered approximately 2 weeks later than the controls, and transgenic lines showing very high *LpTFL1* expression levels still remained nonflowering after exposure to natural vernalization conditions (Danish winter) in two

successive years. There were no other phenotypic effects associated with the *LpTFL* transgene expression during vegetative growth (Jensen *et al.*, 2004).

The *Arabidopsis* TALE-homeobox gene *ATH1* is highly expressed in the shoot apical meristem (SAM) and leaf primordia of the seedlings (Quaedvlieg *et al.*, 1995; Bürglin, 1997). Prior to floral transition, *ATH1* SAM expression is gradually down-regulated to undetectable levels. *Arabidopsis* plants constitutively expressing antisense *ATH1* and *ath1* mutants display a flowering time phenotype that suggests that *ATH1* functions as an inhibitor of floral transition (Van Der Valk *et al.*, 2004). In addition, the tobacco plants constitutively expressing *ATH1* exhibit late flowering as a consequence of impaired GA biosynthesis (Van Der Valk *et al.*, 2004). To delay floral transition in turfgrass, the *Arabidopsis* *ATH1* gene driven by the maize *ub1* promoter, the rice actin *Act1* promoter, or the rice *OSH1* promoter, respectively, was introduced into perennial ryegrass. In *ATH1*-expressing plants heading was delayed, and in a number of cases the plants never flowered at all. Such non- or late heading was accompanied by the outgrowth of normally quiescent lateral meristems into extra leaves, resulting in a leafy growth habit. When eventually heading, these plants generally produced a reduced number of inflorescences (Van Der Valk *et al.*, 2004).

2.3.4.3 Down-regulation of pollen allergens

Perennial ryegrass (*L. perenne* L.) and Italian ryegrass (*L. multiflorum* Lam.) are major sources of allergenic pollen causing hay fever and seasonal allergic asthma in humans during the flowering period in spring and summer in cool temperate climates. To reduce the allergic potential of ryegrass pollen, the expression of three main allergens of ryegrass pollen, proteins Lol p 1 (35 kDa), Lol p 2 (11 kDa), and Lol p 5 (31 kDa), have been down-regulated in transgenics. The introduction of the *Lol p 1* and *Lol p 2* transgenes in antisense orientation under control of the maize pollen specific *Zm13* promoter into perennial ryegrass and Italian ryegrass led to a reduction in accumulation levels of Lol p 1 and Lol p 2 allergens in pollen of transgenic plants, as

demonstrated by immunoblots using polyclonal antibodies raised against the recombinant Lol p 1 and Lol p 2 allergens as well as with sera from grass pollen-sensitized patients (Petrovska *et al.*, 2004). Similarly, down regulation of the Lol p 5 allergen in annual ryegrass *L. rigidum* L. was achieved with an antisense construct under control of a pollen-specific promoter, *Ory sl*. Immunoblot analysis of proteins with allergen-specific antibodies did not detect Lol p 5 in the transgenic pollen. The transgenic pollen showed remarkably reduced allergenicity as reflected by low IgE binding capacity of pollen extract as compared with that of control pollen. The transgenic ryegrass plants in which *Lol p 5* gene expression is perturbed showed normal fertile pollen development (Bhalla *et al.*, 1999).

2.4 Site-Specific DNA Recombination for Genome Modification in Turfgrass

Site-specific DNA recombination is a precisely defined DNA rearrangement between two appropriate target sequences. A number of site-specific recombinases have been identified in bacteria and yeast that catalyze DNA recombination between specific target DNA sites (Ow and Medberry, 1995), producing various recombinant molecules according to the orientation of their specific target sites. Recombination between directly oriented sites on a circular molecule leads to excision of the DNA between them, whereas recombination between inverted target sites causes inversion of the intervening DNA. Recombination between sites on separate molecules produces a co-integration event. Some site-specific recombination systems have been shown to function efficiently in heterologous cellular environments. For example, FLP/*FRT* from the 2 μ m plasmid of *Saccharomyces cerevisiae* (Broach *et al.*, 1982), or Cre/*lox* from *E. coli* phage P1 (Austin *et al.*, 1981) have been demonstrated to catalyze DNA recombination in a large number of plant species, including agriculturally important crops (reviewed in Luo and Kausch, 2002; Hu *et al.*, 2006), providing excellent genetic tools for controlled modification of plant genomes including chromosomal deletions, inversions, transpositions (Ow, 1996; Luo and Kausch, 2002), or site-specific gene targeting (Albert *et al.*, 1995; Vergunst and

Hooykaas, 1998; Vergunst *et al.*, 1998; Srivastava and Ow, 2002).

To study the feasibility of using FLP/*FRT*, a site-specific DNA recombination system originally identified in yeast, for controlled genome modification in plants of turfgrass species, suspension cell cultures of creeping bentgrass (*A. stolonifera* L.) and Kentucky bluegrass (*P. pratensis*) were co-transformed with a FLP recombinase expression vector and a recombination-reporter test plasmid containing β -glucuronidase (*gusA*) gene, which was separated from the maize *ubi1* promoter by an *FRT*-flanked blocking DNA sequence to prevent its transcription. GUS activity was observed in co-transformed cells when conducting transient assays. PCR and Southern analyses indicated that FLP-mediated excision of the blocking sequence had brought into proximity the upstream promoter and the downstream reporter gene, resulting in GUS expression. Functional evaluation of the FLP/*FRT* system using transgenic creeping bentgrass plants stably expressing FLP recombinase confirmed the observation from the experiment using suspension cell culture (Luo and Kausch, 2002; Hu *et al.*, 2006). These results indicate that FLP/*FRT* system is a useful tool for genetic manipulation of turfgrass, pointing to the great potential of further exploiting the system for genome modification in perennials.

2.5 Molecular Strategies for Transgene Containment in Turfgrass

To realize the full potential of agricultural biotechnology, the ecological, commercial, and public interest concerns about transgene escape to wild and nontransformed plants through the dispersal of viable pollen and/or dissemination in seed must be addressed (Wipff and Fricker, 2001; Adam, 2002; Dale *et al.*, 2002; Daniell, 2002; Watrud *et al.*, 2004). This is especially important when the target plant species are perennials and outcrossing, such as turfgrasses. Field trial (Wipff and Fricker, 2001) and landscape-level studies (Watrud *et al.*, 2004) on pollen-mediated gene flow from genetically modified creeping bentgrass (*A. stolonifera* L.), one of the first wind-pollinated and highly outcrossing transgenic perennial crops being developed for commercial use have presented evidence that documents multiple instances

at numerous locations of long-distance viable pollen movement from multiple source fields of genetically modified creeping bentgrass. A recent study using glyphosate-resistant creeping bentgrass plants expressing the *CP4 EPSPS* transgenes demonstrates that transgene flow from short-term production can result in establishment of transgenic plants at multikilometer distances from genetically modified source fields or plants. Selective pressure from direct application or drift of glyphosate herbicide could enhance introgression of *CP4 EPSPS* transgenes and additional establishment. Obligatory outcrossing and vegetative spread could further contribute to persistence of *CP4 EPSPS* transgenes in wild *Agrostis* populations, both in the presence or absence of herbicide selection (Reichman *et al.*, 2006). These findings suggest that implementation of strategies for gene containment in transgenics might be useful for field release of any transgenic turfgrass species in the near future.

2.5.1 Male sterility for gene containment

Male sterility resulting from the lack of significant numbers of viable pollen grains, when linked to the genes of interest that are to be transferred into the target species, provides an effective way for interrupting gene flow. The feasibility of using cell-specific expression of cytotoxic molecules and an antisense gene that controls male fertility to block pollen development in transgenic turfgrass has been studied (Luo *et al.*, 2004a, 2005). To induce male sterility in turfgrass, a 1.2-kb regulatory fragment (TAP) of the rice *RTS* gene that is exclusively expressed in the anther's tapetum during meiosis (Luo *et al.*, 2006) was fused with two different genes. One is a ribonuclease gene for barnase from *Bacillus amyloliquefaciens* (Hartley, 1988) and the other, the antisense of the rice *RTS* gene essential for male fertility (Luo *et al.*, 2006). Both chimeric genes were linked to the *bar* gene for selection by resistance to the herbicide glufosinate. *Agrobacterium*-mediated transformation of creeping bentgrass (cv. Penn A-4) with both constructs resulted in herbicide resistant transgenic plants that were also 100% pollen-sterile. Mendelian segregation of herbicide resistance and male sterility was observed in T₁ progeny derived from crosses with wild-

type plants. Controlled self- and cross-pollination studies showed no gene transfer to nontransgenic plants from male-sterile transgenics. Thus, male sterility can serve as an important tool to mitigate transgene escape in bentgrass. It could also provide a tool in controlling gene flow in other perennial species using transgenic technology for trait improvement.

2.5.2 Controlled total sterility for gene containment

Another molecular strategy, which combines manipulation of genes involved in the transition from vegetative to reproductive growth and the use of site-specific DNA recombination systems for controlled total vegetative growth has been proposed for mitigating transgene escape in perennials (Oliver *et al.*, 2004; Hu *et al.*, 2006). In this method, a controlled total vegetative growth can be achieved by using down-regulation of a plant gene, the *FLORICAULA/LEAFY* (*FLO/LFY*) homolog, which determines the vegetative to reproductive developmental transition of meristems (Coen *et al.*, 1990; Weigel *et al.*, 1992), together with FLP/*FRT* recombination system for prevention of transgene escape from genetically engineered turfgrass to wild and nontransformed species. Transgenic turfgrass plants containing a construct in which a constitutive promoter is separated from either an RNAi (RNA interference) construction or an antisense of the turfgrass *FLO/LFY* homolog gene by a blocking sequence flanked by directly oriented *FRT* sites can be generated and expected to flower normally to produce seeds. When crossed to a plant expressing transgene of interest together with the FLP recombinase transgene, FLP should excise the *FRT*-flanked blocking fragment thus bringing the RNAi construction or the antisense of turfgrass *FLO/LFY* homolog proximal to the upstream constitutive promoter, activating the constitutive expression of the RNAi or antisense construction for *FLO/LFY*. This in turn will down-regulate the expression of the endogenous *FLO/LFY* genes rendering the plant incapable of producing flowers. The vegetative growth habit of the hybrid retains its commercial application but is incapable of transferring transgenes to neighboring grasses or weedy relatives.

3. REGULATION OF GENETICALLY ENGINEERED TURFGRASSES

As with any genetically engineered (GE) plant in the United States, GE turfgrasses are regulated under the 1986 Coordinated Framework for Regulation of Biotechnology. The US government agencies responsible for oversight of the products of agricultural modern biotechnology are the US Department of Agriculture's Animal and Plant Health Inspection Service-Biotechnology Regulatory Services (USDA-APHIS) (http://www.aphis.usda.gov/biotechnology/brs_main.shtml), the US Environmental Protection Agency (EPA) (<http://www.epa.gov/pesticides/biopesticides>), and the Department of Health and Human Services' Food and Drug Administration (FDA) (<http://www.cfsan.fda.gov>).

The Federal laws currently used to regulate the products of modern biotechnology are the Plant Protection Act (PPA), the Federal Food, Drug, and Cosmetic Act (FFDCA), the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA), and the Toxic Substances Control Act (TSCA). Regulations have been developed under these statutes as needed to address GE products. New regulations, policy statements, and guidelines continue to be developed as needed.

The responsibilities of USDA, FDA, and EPA in the regulatory oversight of GE crop plants and their products are complementary, and in some cases overlapping. USDA-APHIS has jurisdiction over the planting of GE plants. FDA has jurisdiction over food and feed uses of all foods from plants. EPA has jurisdiction over planting and food and feed uses of pesticides engineered into plants (these are referred to as plant-incorporated protectants, or PIPs). These PIPs would include resistance to diseases and other pests. In addition to PIPs, EPA has jurisdiction over labeling or use of herbicides to be applied on GE herbicide-tolerant plants.

Depending on its characteristics and intended use, a product may be subject to review by one or more of these agencies. A food crop plant being developed using genetic engineering to produce a pesticide in its own tissue provides an example that is reviewed by all three regulatory agencies. A common example of this type of product development is corn into which scientists have inserted a gene isolated from the soil bacterium,

Bacillus thuringiensis (*Bt*). The *Bt* gene encodes a protein that acts as a pesticide for Lepidoptera and when this gene is inserted into the plant, the plant can then produce the *Bt* pesticidal substance.

USDA-APHIS under the PPA would regulate the experimental corn as a "regulated article". USDA-APHIS oversight begins early in the development cycle and continues until the developer applies for and is granted nonregulated status for the plant provided it can be shown that the plant is not a plant pest. Until such time as the developer is granted nonregulated status for the plant, USDA-APHIS authorizes interstate movement, importation, and field-testing of the plant.

EPA regulates the distribution, sale, use, and testing of the pesticidal substance. In the case of *Bt* in corn, EPA regulates the *Bt* because it is a pesticide. EPA generally controls the field testing of pesticides through an Experimental Use Permit (EUP). In order to legally sell or distribute the pesticide in commerce, the company must register the pesticide with EPA. Through the registration, EPA can establish the conditions of commercial use. EPA is also responsible for setting the amounts or levels of pesticide residue that may safely be in food or feed (i.e., establish a tolerance). EPA may allow an exemption from the requirement to set such a tolerance if it can be shown that there is no food or feed safety issues associated with the pesticide.

Developers of the *Bt* corn also consult with FDA about possible other unintended changes to the food or feed, for example possible changes in nutritional composition or levels of natural toxicants. Although this consultation is voluntary, all of the GE food/feed products commercialized to date have gone through the consultation process. The consultation with FDA serves to ensure that safety or other regulatory issues that fall within the agency's jurisdiction, including appropriate labeling of the food, are resolved prior to commercial distribution.

In the case of GE turfgrasses, these plants are not generally developed for food or feed purposes. If this is the case, FDA would not be involved in the review of the GE plant. However, any of the turfgrasses could be used for forage to be fed to animals. This may happen especially during seed production when the straw is removed from the fields after the seed harvest. In many cases, the

straw is fed to animals. Therefore, if there is a possibility that the GE plants will be used for food or feed, it is highly recommended that the FDA review the product.

Disease resistance and insect resistance have always been important goals in the improvement of turfgrasses. Since these characteristics are considered plant-incorporated pesticides (PIPs), both EPA and APHIS would be involved in regulating these plants. EPA requires EUPs for testing an unregistered PIP or an unregistered use of a PIP on a cumulative total of over 10 acres. USDA-APHIS requires permits for all field testing of regulated GE turfgrass plants regardless of the size of the field trial. APHIS and EPA would both review their respective applications and commercial releases for potential impacts on nontarget organisms such as beneficial insects and threatened and endangered species.

Weed control has always been an important management component for high quality turf and, therefore, incorporation of tolerance to a specific herbicide into a turfgrass could be an important goal for turfgrass variety improvement. In the case of GE herbicide tolerance, USDA-APHIS would be the lead agency in regulating these plants with permits required for all field testing, movements, and importations. Since weeds need to be controlled for optimum turf performance for the herbicide-tolerant grass, the herbicide needs to be applied at least occasionally to the turf. Even if this specific herbicide is registered for many different uses, this new use for its application on this new herbicide-tolerant variety needs to be approved by EPA, and this review and approval would be reflected in the labeled use for this herbicide.

Finally, in the case of GE modifications for other desirable turfgrass characteristics such as less vertical growth, tolerance to various stresses (heat, cold, drought, wear, etc.), nutrient use efficiency, etc., USDA-APHIS would be the only agency regulating field testing, movements, and importations assuming it is not used for feed.

3.1 Regulatory Considerations During Field Testing of Transgenic Turfgrasses

Since USDA-APHIS is the regulatory agency most involved in all phases of field testing of GE plants before commercial release, this discussion

will address only USDA-APHIS considerations. APHIS protects agriculture and the environment by ensuring that biotechnology is developed and used in a safe manner. Through a strong regulatory framework, the Biotechnology Regulatory Services (BRS) program of USDA-APHIS ensures the safe and confined introduction of new GE plants with significant safeguards to prevent the accidental release of any GE material. APHIS regulations require that a developer of a GE plant have BRS authorization prior to importing, moving interstate or field testing the GE plant. Applicants must submit all plans for movement, importation, or field testing for thorough review by regulatory scientists. Those scientists will then evaluate the proposed procedures and assess any potential risks. The developer must adhere to certain measures that ensure adequate confinement of the organism. BRS also works closely with states to be sure that they are aware of field tests taking place within their jurisdiction and to allow them to request any additional conditions they may require. To ensure compliance with the permit conditions, BRS inspects field test sites and audits records.

Because each species presents its own unique challenges and opportunities, and regulations (The regulations are in 7 CFR 340 http://www.access.gpo.gov/nara/cfr/waisidx_05/7cfr340_05.html) and guidelines dealing with GE organisms tend to change frequently for this fast changing science, BRS encourages developers of GE turfgrasses to visit the BRS website (<http://www.aphis.usda.gov/biotechnology/brs.main.shtml>) and with BRS scientists to fully understand the requirements and expectations that need to be met before a GE turfgrass can be field tested and eventually commercialized. Permits for field testing GE turfgrasses may require up to 120 days to process so substantial advanced planning is needed. However, if the permit application involves a new species or a novel modification that raises new issues not previously addressed by APHIS, an environmental assessment may need to be prepared which may require additional time for processing the permit. Previously approved field tests and associated environmental assessments can be viewed online at the website for Information Systems for Biotechnology (<http://www.isb.vt.edu>). Examining previous environmental assessments will give the developer

a flavor for the types of information considered for an environmental assessment.

For submitting a permit application, the present requirements call for submitting an APHIS Form 2000 (Since regulations and guidelines change frequently, please check the website noted below. Beginning 2007 the permit application may be submitted electronically.) Following are some key features for submitting a permit for field testing a regulated GE plant: the responsible person needs to be a US resident or designate an agent who is a US resident; confidential business information may be claimed (see the BRS website for detailed guidance); scientific and common names of the donor organisms (The organisms from which the DNA was obtained—the typical construct may have pieces of DNA (promoter, gene of interest, terminators, selectable markers, etc.) from several organisms); scientific and common names of the recipient plant; vector or vector agents (biolistics, disarmed *Agrobacterium tumefaciens*, etc.); names or line numbers of the regulated article; a description of the anticipated or actual expression of the altered genetic material in the regulated article and how that expression differs from the expression in the nonmodified parental plant (morphological characteristics, physiological activities, growth characteristics, etc.); a detailed description of the purpose for the field test including a detailed description of the field test design; the proposed maximum size of the field test; the proposed earliest date of the field planting and the length of time requested for the permit (the length of time that the field test will exist); the proposed number of plantings; a detailed description of the field trial location; a detailed description of the procedures that will be used to prevent the release or movement of the regulated article outside of the test area (this includes monitoring for the regulated article at the end of the field test); and a detailed description of the proposed method of final disposition of the regulated article. For full details in applying for a permit, check the BRS website (http://www.aphis.usda.gov/permits/brs_epermits.shtml).

With the advent of genetically engineered perennial grasses and the availability of single herbicide tolerance genes and other easily detectable molecular markers, extremely precise information is becoming available on pollen flow for perennial grasses. These data are generally

much more precise than the data available based on morphological characteristics of which the precision may be as small as 0.1% (parts per thousand), whereas the data from single herbicide tolerance genes or molecular markers may be as precise as 0.0001% (parts per million). With additional data becoming available on pollen flow for creeping bentgrass (Wipff and Fricker, 2001; Wipff, 2002; Belanger *et al.*, 2003; Watrud *et al.*, 2004; Petition 03-104-01p), tall fescue (Wang *et al.*, 2004), and Kentucky bluegrass (Johnson *et al.*, 2006) and on possible creeping bentgrass seed movement (Reichman *et al.*, 2006), APHIS is updating its guidance for field testing of wind-pollinated perennial grasses. These recent studies have had very similar results. As with most plants, cross-pollination with other plants is most likely between sexually compatible plants that are closest to each other. With wind pollination, the maximum distance that viable pollen may pollinate sexually compatible plants is highly dependent on the speed and direction of air movement. In addition, the amount of viable pollen produced has an effect on the farthest distance that one or more successful pollinations will most likely take place. In all of the pollination studies cited above, only Watrud *et al.* (2004) studied a creeping bentgrass pollen source that greatly exceeded 500 pollen source plants with that study measuring pollen flow from 162 ha (400 acres) with a successful cross-pollination documented at 21 km. The greatest distance found for a successful cross-pollination with one of the smaller studies (Wipff, 2002) was a distance of 426 m with a pollen source of 298 plants.

Perennial grass species used for turf and forage have many characteristics in common. They generally are perennial, wind pollinated, small seeded, easily propagated vegetatively, spread vegetatively by stolons and/or rhizomes (and to some extent by tillers), tolerant of traffic, mowing, grazing, and burning, and tolerant of cold and/or heat stress by becoming dormant. Many of the perennial grass species have some seed dormancy, and many are easily propagated by seeds. These same characteristics are typical of perennial grass species used for forages. In fact, many turfgrass species are used for forage as well as for turf. For the species cited above in the pollen flow studies, creeping bentgrass is used mainly for turf purposes but it has been used frequently for forage

purposes, tall fescue is used for forage and turf, and Kentucky bluegrass is used mainly for turf and is frequently found in pastures and other grazed areas.

All of these characteristics of perennial grasses need to be taken into account when considering confinement procedures for field testing GE turfgrasses. Confinement procedures need to take into consideration any means of gene flow—pollen, seed, and vegetative parts. Testing of turfgrasses is generally conducted in two distinct phases—turf performance and seed production.

When testing its turf performance, it is mowed one to several times a week resulting in the removal of all or most of its flowers. If this is the case, any concerns about pollen flow or seed movement are completely eliminated or greatly reduced, but concerns about vegetative movement and volunteer plants after the removal of the test would still need to be addressed. Various procedures can possibly be used to assure confinement: a nontransgenic border area or fallow zone surrounding the test to allow personnel to identify and control any transgenic plants that may be growing outside of the test; all equipment used in the test area is cleaned inside the test plot or border area before it is moved off the test site; access to the site is restricted to authorized personnel who have been trained to follow suitable procedures to minimize the spread of the regulated article; in addition to the border area, an additional isolation area surrounding the test area which is monitored for the presence of sexually compatible plants (plants that have the potential to cross with the regulated article and produce viable offspring) and if present are destroyed or prevented from flowering; and upon termination of the trial, monitor the regulated trial area for volunteers for an agreed period of time. For clarification, the regulated trial area includes the test area and the surrounding border area.

For testing during the seed production phase, pollen flow and seed movement need to be addressed as well. Possible methods for limiting pollen flow include: using sterile plants that will not produce pollen or seed; using male sterile plants; bagging the flowers/seed heads; covering all plants with a tight mesh netting that will restrict pollen flow; growing plants in an isolated area where no sexually compatible plants are

growing in the immediate area—this includes seed fields of the same or related species, feral plants of the same or related species, and plants of “wild” related species; and restricting access to the site to authorized personnel who have been trained to follow suitable procedures to minimize the spread of pollen on clothes and equipment. For growing the flowering plants in isolation to be effective, scouting for sexually compatible plants at the future site of a proposed trial a year before installing the test is helpful, and then monitoring for sexually compatible plants in the isolation area during the flowering period of the trial itself shortly before or in the early flowering period and destroying any plants found during these monitoring periods would be required.

Possible methods for limiting seed movements include: using sterile plants that will not produce seed; bagging the flowers/seed heads; covering all plants with netting that will restrict seed movement by wind or birds; placing fence around the trial that would restrict animals and unauthorized individuals from walking across the trial; placing harvested seed heads directly into a container instead of laying seed heads down to dry; using dedicated equipment to avoid mixing regulated article with unregulated material; restricting access to the site to authorized personnel who have been trained to follow suitable procedures to minimize the spread of seed on clothes and equipment; conducting the trial in an inhospitable environment so escapes are unlikely to establish and feral populations are unlikely to exist; using a nontransgenic border area or fallow zone surrounding the test to allow personnel to identify and control any transgenic plants that may be growing outside of the test—the border will also provide an area to service and clean equipment, and for a staging area for placing seed prior to planting or placing harvest containers; having a substantial isolation area in addition to the border between the trial and any harvested crop, especially for any seed crop of perennial grasses; and upon termination of the trial, monitoring the regulated trial area for volunteers for an agreed period of time. Again, the regulated trial area includes the test area and the surrounding border area.

All of the confinement measures mentioned above are possible suggestions to consider when

planning to install and conduct trials of transgenic turfgrasses. But for each species, possibly the transgenic characteristic, and the size of the trial, the confinement measures may vary. The length of any recommended monitoring period depends heavily on the seed dormancy characteristics of each species. Therefore decisions on the specific requirements need to be made on a case-by-case basis.

3.2 Obtaining Nonregulated Status and Commercialization of Transgenic Turfgrasses

As with any variety development program, a point is reached where the performance data obtained in various trials appear to justify a commercial release of the developed variety. However, unlike a conventionally developed variety in which no genetic engineering techniques were used, in addition to convincing only the potential buyers or customers of the new variety's advantages, three different government agencies may need to be convinced that it is safe to consume as food or feed (FDA), it has no pesticidal properties that make it harmful to the environment, unsafe to consume, or requires a quantity of a pesticide that is considered to be detrimental to the environment (EPA), and/or it is not detrimental to agriculture or the environment (USDA). For the USDA, a person needs to submit a petition for determination of nonregulated status. If approved, the new variety is considered deregulated, and the product and its progeny would no longer require USDA-APHIS review for movement or release in the United States.

In this petition, the developer should include the following: the purpose or rationale for the petition; a description of the biology of the plant before it was genetically engineered; description of the transformation system; a detailed description of the donor gene(s), other DNA sequences and its products along with the map of the construct used in the transformation; molecular characterization analysis of the DNA insert in the recipient (insert length, number, and partial pieces of the construct, presence of the plasmid backbone, and stability of the insert); a detailed breeding diagram of the selection practices and procedures used to develop each generation,

and population of plants used to provide data in the petition; inheritance of the transgenic trait; differences between the GE plant and the original plant; a description or rationale for the use of the control varieties or lines used in the comparison of the regulated article to the unmodified recipient (this may be the same line as the regulated article without the transgene and/or an array of varieties representative of the species); detailed phenotypic comparisons of the transgenic plant and unmodified recipient for various characteristics—seed germination, seed vigor, seed establishment, seed dispersal, seed dormancy, seed yield, time and length of flowering and seed production period, growth habit, vegetative vigor (horizontal spread, plant height, and/or biomass), tolerance to biotic and abiotic stresses, outcrossing frequency, effect on pollinator species, pollen characteristics (size, shape, amount, stickiness, longevity, etc.), symbionts, asexual reproduction (vegetative and seed), and self-compatibility (<http://www.aphis.usda.gov/brs/canadian/appeannex2e.pdf>, <http://www.cast-science.org/websiteuploads/pdfs/turfbiotech.is.pdf>).

The petitioner may address each of the above topics using the scientific literature and/or test results developed specifically for the petition. These measurements or observations on all of the phenotypic characteristics are useful in the review of the petition for determining the existence of “unintended effects”. From a variety development perspective, almost all of the phenotypic characteristics are noted during the variety testing stages anyway so the documentation of these observations requires only a small additional effort if the tests are well planned in advance of the petition.

All of the field tests conducted under APHIS regulation for this regulated product need to be listed in the petition. All required field-test reports for each of the field tests need to be completed and on file with USDA-APHIS. The petitioner is also required to provide any known information that indicates that the regulated article may pose a greater plant pest risk than that of the unmodified recipient plant.

After reviewing the petition, BRS conducts an environmental assessment in compliance with the National Environmental Policy Act to analyze the potential impacts the GE organism may have on agriculture and the environment. This assessment

includes a wide variety of environmental parameters and looks for possible effects to threatened and endangered species. After the completion of the assessment by BRS, it is posted on the Web along with a copy of the developer's petition (with all confidential business information deleted) and made available for a 60-day public comment period through the *Federal Register* announcement. Following these procedures, BRS then decides to approve or deny the petition. For obtaining details on completing the petition, guidance is provided on the BRS website (http://www.aphis.usda.gov/biotechnology/brs_main.shtml) indicating the type of molecular details and the agronomic data that are helpful in evaluating the petition. The past petitions approved by BRS are also available through the BRS website.

4. FUTURE PERSPECTIVES

The rapid development of turfgrass genetic transformation technologies has made it possible to apply biotechnological approaches for trait modifications in a large number of grass species. The many promising data obtained so far point to the great potential of commercialization of new turfgrass cultivars with genetically improved traits. However, concerns on transgene flow from genetically modified plants to compatible wild species and unintended ecological consequences of potential transgene introgression impose hurdles for the deregulation of any transgenic perennial species. Development and implementation of molecular strategies for gene containment in genetically modified transgenic plants with improved performance may facilitate public acceptance and commercialization of GM products in turfgrass species. Besides the use of strategies involving manipulation of genes that control plant reproductive growth for gene containment, chloroplast genetic engineering to promote maternal inheritance of transgenes is a promising option for prevention of gene flow through pollen dispersion. Maternal inheritance of cytoplasmic organelles is shared by plant (chloroplast) and animal (mitochondria) systems. The prevalent pattern of plastid inheritance found in majority of angiosperms is uniparental-maternal and chloroplast genomes are maternally inherited in

most crops (Daniell, 2002). Maternal inheritance of transgenes and prevention of gene flow through pollen in chloroplast transgenic plants have been successfully demonstrated in several plant species, including tobacco and tomato (Daniell *et al.*, 1998; Ruf *et al.*, 2001). In addition to its potential for gene containment, chloroplast engineering offers several other advantages, including a high level of transgene expression, multigene engineering in a single transformation event, lack of gene silencing, position effect, pleiotropic effects, and undesirable foreign DNA. Chloroplast engineering also can greatly enhance the capability of some turfgrass species as potential bioreactors for large-scale production of industrial enzymes, biodegradable plastics, pharmaceuticals, vaccines, and antibodies. With the success of chloroplast engineering in the first monocot species, rice (Lee *et al.*, 2006), and the availability of creeping bentgrass chloroplast genome sequence, the very first in turfgrass species (Saski *et al.*, 2007), chloroplast engineering in turfgrass species could be expected in the very near future.

Although genomics studies in turfgrass species lag behind that of other agriculturally important food grasses due to the complex genetic constituents of turf species, and the lack of substantial public funding for support, data generated from major crop plants (rice, wheat, and maize), especially the completion of the genome sequencing of the first grass species, rice, provide invaluable information in developing molecular and genomics tools for gene discoveries and for better understanding of molecular mechanisms defining plant resistance to biotic and abiotic stresses as well as other biological processes. This will result in more effective tools and strategies in genetically improving turfgrass for enhanced stress tolerance and desired plant morphologies using biotechnological approaches.

ACKNOWLEDGMENTS

The research on turfgrass tissue culture and transformation has been supported by NCSU Center for Turfgrass Environmental Research and Education, the NC Turfgrass Foundation, US Golf Association, and HybriGene (Kinston, RI) to R.Q., and by the USDA-BRAG grant #2005-39454-16511 and CREES SC-1700315 to H.L.

1. INTRODUCTION

Over the past 20 years, several *Populus* species (commonly known as poplars and encompassing aspens, cottonwoods, and hybrid poplars) have been the most frequently used trees for transgenic research. Among commercially important tree species, poplars are relatively easy to transform and of great economic importance to forest product industries. Although it is difficult to discern from which of the above qualities the preponderance of poplar research activity is a result, poplars are nonetheless regarded as the most suitable model system for tree biotechnology research (Bradshaw *et al.*, 2000; Taylor, 2002; Tuskan *et al.*, 2003). A large number of review articles (e.g., Bradshaw, 1996; Bradshaw *et al.*, 2000; Rishi *et al.*, 2001; Confalonieri *et al.*, 2003) as well as monographs (e.g., Stettler *et al.*, 1996; Klopfenstein *et al.*, 1997) has recently been published on the biology and biotechnology of poplars. This review will attempt to compile and summarize the published literature and research findings in order to serve as an information resource on transgenic poplars.

1.1 History of Poplar Cultivation, Breeding, and Utilization

Historical records indicate that since the late 17th century, there have been poplar plantations across Europe, Asia, and the Middle East, although poplar trees have likely been utilized by humans since prehistorical times (<http://www.cnr.umh.edu/fr/publications/proceedings/papers/Stoffel-Duluth.pdf>). A number of legends, myths, and beliefs are associated with poplars, such as the legend that the cross on which Christ was crucified was made from the wood of a trembling aspen, all of which now tremble with grief and remorse because of the event. A German legend describes the Holy Family as walking in a forest where all trees except aspen bowed before them to show respect. The Holy Child cursed the tree, and the leaves began to, and have ever since, trembled with fear. Poplars were selected as the symbol of liberty during the French revolution of 1789 (McNabb, 1997). In Europe, spontaneous hybrids of the imported *P. deltoides* and the European native black poplar, *P. nigra*, were discovered around 1775 (McNabb, 1997). Initially

named black Italian poplars, they were later renamed *Populus* \times *canadensis* by Mönch in 1795. Hybrid poplars were also depicted by the notable French impressionist painter Monet in such works as *Poplars on the Epte* and *Poplars along the River Epte*. Although naturally occurring poplar hybrids were common in 18th and 19th century Europe, systematic poplar breeding began only in the early 20th century at the Kew Botanical Gardens, England. The first recorded attempt of crossing poplars was made between flowers of *P. angulata* with pollen of *P. trichocarpa*, with the resultant hybrid named as *P. generosa*. Subsequent poplar breeding programs began around 1920 in Canada, United States, Denmark, and France (McNabb, 1997).

Over the past 50 years, hybrid poplars have been planted across the US landscape and windbreak trees. Poplar breeding programs focused on both the hybrid vigor of interspecific poplar hybrids and their clonal selections (Bisoffi and Gullberg, 1996). The spontaneous natural hybrids that were recognized early in 20th century were used as a logical starting point for breeding programs. The relative ease of clonal propagation of poplars assisted in the incorporation of clonal selection in poplar breeding programs. Recently, there has been an increased interest in poplar breeding in the North America. These efforts have focused on producing vigorous *P. tremuloides* and *P. tremula* hybrids (Li, 1995; Bradshaw, 1996). Additionally, there have been cooperative breeding programs between universities and pulp industries in the Pacific Northwest region of North America. These efforts have produced *P. trichocarpa* \times *P. deltoides* hybrids (<http://www.cof.orst.edu/coops/tbgc/index.htm>), and also hybrids of *P. trichocarpa* \times *P. maximowiczii*; *P. trichocarpa* \times *P. nigra*, and *P. deltoides* \times *P. nigra* (Stettler *et al.*, 1996; Zsuffa *et al.*, 1996).

A major consolidation of global poplar research was initiated through the establishment of the International Poplar Commission (IPC) in 1947, which is one of the technical statutory bodies of the Food and Agriculture Organization of the United Nations (FAO). Their mandate is to promote cultivation, conservation, and utilization of members of the family Salicaceae, which includes poplars and willows (<http://www.fao.org/forestry/site/ipc/en>). IPC assists researchers in the direction and coordina-

tion of scientific efforts and promotes conservation and exchange of poplar germplasm among the member nations. The IPC also supports research and management activities that explore issues of concern to its 37 member countries through six working parties—harvesting and utilization; diseases; insect pests; genetics; conservation; and improvement; production systems, and environmental applications. IPC also promotes poplars and willows as fast-growing trees that provide a wide range of goods, including industrial roundwood (sawn timber, peeler logs, and pulpwood), fuelwood, poles and fodder, and services such as soil erosion prevention, and aesthetic value. Moreover, the adaptability of poplars to a wide range of climatic and soil conditions has led to their widespread use in developed and developing countries. Poplars and willows play an important role in rural life in countries with transition economies. Although poplar cultivation has been traditionally integrated into many temperate and subtropical agricultural systems, the use of poplars and willows as biomass for renewable energy is a novel application (Dinus *et al.*, 2001).

Research specific to Short Rotation Woody Crops (SRWCs) such as hybrid poplar has been taking place in the Lake States of the United States for the last 25 years (Dinus *et al.*, 2001). SRWCs are seen as a way to grow more wood fiber on less land in order to reduce potential conflicts between increasing demand for wood fiber and other forest uses. Researchers felt that optimum tree growth could be realized by borrowing the intensive cultivation techniques common in other forms of agriculture, including the use of hybrids. Most of this research involved hardwoods, particularly poplars, because of their rapid growth. Interest in SRWCs intensified in 1977 when the oil embargo provided an impetus for additional funding from the US Department of Energy (DOE) to consider wood as an alternative to fossil fuels. With the current petroleum crisis, there is renewed interest in poplar as bioenergy crops.

1.2 Botanical Classification of Poplars

Typically, all members of the genus *Populus* are fast-growing trees with a single trunk. They multiply naturally through stump sprouts or root suckers. Poplars belong to the family Salicaceae

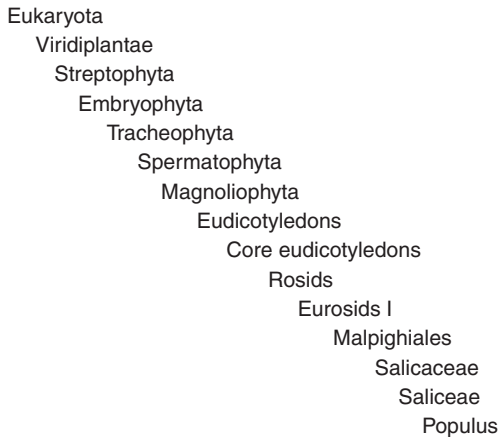

Figure 1 Botanical classification of *Populus*

under the order Malpighiales and are closely related to willows. Figure 1 shows a currently accepted classification system of poplars (Wheeler *et al.*, 2000).

The precise worldwide number of poplar species is difficult to determine. This is due to several reasons: First, the various poplar species are widely distributed throughout the world; second, they actively hybridize with one another, that confounding taxonomic classification; and lastly, they have been profligately imported and exported around the globe, blurring native species boundaries. As per Zsuffa (1975), numerous synonyms exist for the same species, and hybrids and cultivated varieties have often been wrongly named as species. Although the actual number of species belonging to the genus *Populus* is, and continues to be, a highly debatable subject because of intense interspecific hybridizations, Eckenwalder (1996) proposed that the genus *Populus* contains approximately 30 species belonging to six sections. These sections were proposed on the basis of the morphological characteristics of stamens, carpels, seeds, bracts, leaves, and buds (Eckenwalder, 1996). Five of these sections are: *Turanga*, *Leuroides*, *Aigeiros*, *Tacamahaca*, and *Populus*. In the past, a sixth, single-species section has often been proposed to resolve classification problems. For example, section *Abaso* was proposed to accommodate *Populus mexicana* that seems to be weakly related to other species of section *Aigeiros*, in which it was previously placed (Eckenwalder, 1996). Over 90% of the poplar

cultivation throughout the world comes from the species and hybrids in the section *Aigeiros* (Thielges, 1985). This is perhaps due to ease of inter- and intrasectional hybridization within and between the *Aigeiros* and *Tacamahaca* sections, their adaptability in the temperate and subtropical zones, and their ease of vegetative propagation (OECD, 2000). Table 1 shows Eckenwalder's classification of this genus along with distribution of some representative poplar species in each section.

A large number of useful (natural and artificial) intra- and intersectional poplar hybrids are available and being used in cultivation. Table 2 lists some of these poplar hybrids as described in Organization for Economic Cooperation and Development (OECD) report (2000).

As stated previously, there are five major sections of the genus *Populus*: *Populus* (aspens), *Tacamahaca* (Balsam poplars), *Aigeiros* (Cottonwoods), *Turanga* (subtropical poplars), and *Leuroides* (Big leaf poplars). Extensive crossability data exist among species in the *Populus*, *Tacamahaca*, and *Aigeiros* sections, but few data are available for those in section *Turanga* and *Leuroides* (Zsuffa, 1975). Hybrids between members of the same section are produced easily and are often more vigorous than their parents. For example, hybrids between *P. tremuloides* and *P. tremula* are notably vigorous and those between *P. deltoides* and *P. trichocarpa* produce much larger leaves than their parents, thus increasing their potential for biomass production. Crossing success between sections is variable. Crosses between members of *Aigeiros* and *Tacamahaca* sections are simple to complete, while those between sections *Populus* and *Aigeiros*, and sections *Populus* and *Tacamahaca* are most difficult, typically resulting in nonviable seed or dwarfed seedlings (Zsuffa, 1975).

1.3 Origin and Evolution of Poplars

Poplars are hydrophilic trees that grow in high moisture content soils. Their riparian habit and deciduous nature likely helped preserve leaf samples in the fossil record. Some studies suggest poplars originated in the late Paleocene (58 million years ago; Eckenwalder, 1996). A representative of the *Abaso* section related to modern *P. mexicana* was present in North America but disappeared at

Table 1 Classification, nomenclature, and occurrence of some *Populus* species

Section	Scientific name	Common names	Occurrence
<i>Abaso</i> Ecken.			
	<i>P. mexicana</i> Wesmael		Mexico
<i>Turanga</i> Bunge.			
	<i>P. euphratica</i> Oliv.	Euphrates poplar, bahan	Spain, NE Africa, Asia (China)
<i>Leucoides</i> Spach		Large-leaved poplars	
	<i>P. lasiocarpa</i> Oliv.	Chinese necklace poplar	China
	<i>P. heterophylla</i> L.	Swamp cottonwood, swamp poplar,	USA
<i>Tacamahaca</i> Spach		Balsam poplars	
	<i>P. angustifolia</i> James	Narrowleaf cottonwood, narrowleaf balsam poplar	Southern Sask. and Alberta to southwestern US
	<i>P. balsamifera</i> L.	Balsam poplar	North America
	<i>P. ciliata</i> Royle		Himalayas
	<i>P. laurifolia</i> Ledeb.	Laurel poplar	Eastern Asia
	<i>P. trichocarpa</i> Torr. and A. Gray	Black cottonwood, western balsam poplar	Western Canada and US
<i>Aigeiros</i> Duby		Cottonwoods and black poplars	
	<i>P. deltoides</i> Marsh.	Eastern cottonwood (ssp. <i>deltoides</i>), plains cottonwood (ssp. <i>monilifera</i>), Rio Grande cottonwood (ssp. <i>Wislizenii</i>)	Quebec, Ontario Prairie provinces to Texas SW US
	<i>P. nigra</i> L.	Black poplar, European black poplar	Europe, western Asia
<i>Populus</i> L.		Aspens	
	<i>P. alba</i> L.	White poplar, silver poplar	Central and southern Europe to N. Africa, Central Asia
	<i>P. grandidentata</i> Michx.	Large-tooth aspen, bigtooth aspen, aspen, poplar, popple	Eastern North America
	<i>P. sieboldii</i> Miq.	Siebold aspen, Japanese aspen	Japan
	<i>P. tremula</i> L.	European aspen, tremble, Zitterpappel	Europe, Northern Africa, northeastern Asia
	<i>P. tremuloides</i> Michx.	Trembling aspen, quaking aspen	North America

the end of the Oligocene (23 million years ago) only to reappear during the Holocene (10 000 years ago). Until the late Eocene period (40 million years ago), when swamp poplars of the section *Leucoides* appeared, members of the section *Abaso* were the only poplar species present in North America. During the Oligocene period, fossils of poplars of the section *Tacamahaca*, (which

may be ancestors of two modern-day sections of poplars, *Tacamahaca* and *Aigeiros*), occurred in both the new and old worlds (Collinson, 1992). The representatives of section *Populus*, however, did not appear in fossil records until the early Miocene (20 million years ago). It is, therefore, possible that poplars have inhabited the earth for more than 60 million years.

Table 2 Nomenclature of some selected *Populus* hybrids

Parentage	Hybrid designation	Common name
<i>P. alba</i> × <i>P. adenopoda</i>	<i>P. × tomentosa</i> Carr.	Chinese white poplar
<i>P. alba</i> × <i>P. tremula</i>	<i>P. × canescens</i> (Ait.) Sm.	Grey poplar
<i>P. angustifolia</i> × <i>P. deltoides</i>	<i>P. × acuminata</i> Rydb.	Lance leaf cottonwood
<i>P. balsamifera</i> × <i>P. deltoides</i>	<i>P. × jackii</i> Sarg.	Jack's poplar
<i>P. deltoides</i> × <i>P. nigra</i>	<i>P. × canadensis</i> Moench	Canada poplar
<i>P. deltoides</i> × <i>P. tremuloides</i>	<i>P. × bernardii</i> Boivin	Bernard poplars
<i>P. deltoides</i> × <i>P. trichocarpa</i>	<i>P. × generosa</i> Henry	Interamerican poplars
<i>P. fremontii</i> × <i>P. trichocarpa</i>	<i>P. × parryi</i> Sarg.	Parry cottonwood

1.4 Distribution, Habit, and Habitat of Poplars

The genus *Populus* is widely distributed throughout the northern hemisphere, in both the temperate and colder subtropical zones down to about 30° N of latitude. However, due to intense natural and artificial hybridization and migration across the globe, poplars are now widely planted far beyond their natural range in both the southern and the northern hemispheres.

Poplars are most widely distributed throughout North America, Europe, North Africa, India, China, and Japan (OECD, 2000). *Populus tremuloides* is the most broadly distributed tree species in North America, spanning 110° of longitude and 47° of latitude, and is the second most widely distributed tree in the world. *P. tremula* also has similar wide distribution in Europe. Poplars are a pioneering species that establish following major disturbances like fire. They are also a keystone species that preserves the biodiversity of organisms that inhabit them. Poplars are deciduous trees that are dioecious (i.e., male and female flowers are produced on separate trees), thus resulting in obligate outcrossing. Male and female flowers are produced in pendulous catkins in spring before leaves appear from the flushing vegetative buds. In natural populations, the observed ratio of males to females is generally 1:1, although elevation may affect this ratio. In *P. tremuloides*, females are dominant at lower elevations while the ratio swings to greater than 90% males above 3200 m in the Rocky Mountains (Grant and Mitton, 1979). A continuous stretch of warm temperatures around 12°C for 5–6 days is required for emergence of flowers which are wind-pollinated. Fruiting catkins about 10 cm long are produced on female plants 4–6 weeks after flowering. Each catkin bears several dozen, one-celled capsules, each containing 10–30 small brown seeds, each with tuft of long, white silky hairs attached to one end to aid in long-distance wind dispersal. Poplar trees produce a large number of very small seeds, about 25–50 million. Species in the section *Populus* can produce 6000–8000 seeds per gram, while trees from the *Leucoides* and *Aigeiros* sections produce much larger seeds (Schreiner, 1974). In nature, seeds are viable for a short time and survive only if germinated quickly after dispersal onto moist soil where ample sunlight is available for growth.

Most of the stand growth of poplars is a result of vegetative reproduction from stump sprouts or root suckers rather than from seeds. It has been estimated that in the US, *P. tremuloides* produces 25 000–75 000 suckers per hectares in the Alaska and Great Lakes regions and about half as many in Rockies (Burns and Honkala, 1990). It is believed that in the semi-arid western US, widespread seedling establishment has not occurred since the last glaciation some 10 000 years ago (Einspahr and Winton, 1976). According to Guinness book of world records (<http://www.guinnessworldrecords.com/>), the most massive plant that was ever reported is a network of quaking aspen trees (Pando, i.e., *I spread* in Latin) growing in the Wasatch Mountains, Utah, US, from a single root system, covering 43 hectares (106 acres), consisting of more than 47 000 stems and with a weight in excess of 6 million kilograms, making it the largest known organism (Mitton and Grant, 1996).

Poplars are regarded as small- to medium-sized trees that are fast-growing and short-lived. On average they grow to about 24 m tall with an 18–30 cm d.b.h. (stem diameter at breast height) in about 20 years. Poplars also have a large number of insect, disease, and animal pests ranging from whitetail deer to the poplar willow sawfly to leaf rusts. More information on habit and habitats of a variety of *Populus* species can be obtained at: http://www.na.fs.fed.us/pubs/silvics_manual/volume_2/vol2.Table_of_contents.htm.

1.5 Economic Importance

The economic importance of poplars has been extensively discussed by Balatinecz *et al.* (2001). The most recent and concise information about poplar's worldwide area coverage and wood production is available in the IPC's 2004 report (<http://www.fao.org/forestry/ipc2004>). This report contains a synthesis of progress reports from the 21 member countries and the nonmember country, the Russian Federation, that were present at their 22nd symposium on poplars and willows in Santiago, Chile. According to this report, over 70 million hectares of combined natural poplar populations exist in all these countries. Ninety-seven percent of this growth is present in

three countries: Canada (28.3 million hectares), the Russian Federation (21.9 million hectares), and the US (17.7 million hectares). The next six countries containing significant areas of natural poplar forests are China (2.1 million hectares), Germany (100 000 ha), Finland (67 000 ha), France (39 800 ha), India (10 000 ha), and Italy (7200 ha). The reported global area of poplar plantations, however, was 6.7 million hectares, of which 3.8 million hectares (56%) was planted primarily for wood production and 2.9 million hectares (44%) for environmental purposes. China reported the most planted poplar overall (4.9 million hectares, or 73% of the global total) and India reported 1 million hectares, the second largest area of poplar plantations in the world. The other countries with significant areas of planted poplar included France with 236 000 ha, Turkey with 130 000 ha, Italy with 118 800 ha, Argentina with 63 500 ha, and Chile with 15 000 ha. Only two countries reported significant annual removals of wood from natural stands of poplars: the Russian Federation (100 million m³) and Canada (16 million m³). The five countries that reported annual removals of more than 1 million m³ of poplar wood from planted forests were Turkey (3.8 million m³), China (1.85 million m³), France (1.8 million m³), Italy (1.4 million m³), and India (1.2 million m³).

According to the 2004 IPC report, poplars provide a wide range of wood products (e.g., industrial roundwood and poles, pulp and paper, reconstituted boards, plywood, veneer, sawn timber, packing crates, pallets, furniture); nonwood products (e.g., fodder, fuelwood, bioenergy); and services (e.g., shelter, shade, conservation and protection of soil, water, crops, livestock, and dwellings). Pulp, paper, and cardboard were the most favored end uses in Europe, North America, China, and Argentina. Packaging (pallets, boxes, and crates) was also a favored end use in Europe, the Republic of Korea, the Russian Federation, Canada, China, and India. Reconstituted wood panels were the favored end uses in Germany, Argentina, Canada, the US, Bulgaria, and Italy. Plywood was also a favored end use in India, Italy, Spain, China, Turkey, France, Serbia, Montenegro, and the US. Use of poplars for matches was favored in Chile, the Russian Federation, India, the Republic of

Korea, and Sweden. Furniture manufacturing was generally ranked as a lower priority by most countries except Belgium and Chile. Fuelwood or production of biomass for energy was also generally ranked as a lower priority by most countries; however, it was of significant economic importance in Sweden, the United Kingdom, and Turkey. The other end uses for lumber and general construction were reported as priorities in Turkey, Finland, and Argentina; and handicrafts and wicker work in Chile and the Russian Federation. The Republic of Korea, Serbia, Montenegro, and Sweden highlighted that their principal use of poplar and willow resources was for environmental conservation, thus providing valuable services rather than forest products. In summary, various countries have region-specific uses of poplars, although in most cases the commercial importance of poplars by major forest product industries is regarded as modest as compared to pines and eucalypts (Bradshaw *et al.*, 2000).

1.6 Cytological and Genomic Features of Poplars

Generally, all poplars are diploid species with $2n = 38$ chromosomes (Bradshaw *et al.*, 2000). Polyploid poplar trees have been rarely reported in a few species (Darlington and Wylie, 1956). The first triploid forest tree reported was a clone of *P. tremula* (Müntzing, 1936). Several other natural triploid clones have since been found in both *P. tremula* and *P. tremuloides*, usually exhibiting larger leaves and exceptional growth (Einspahr *et al.*, 1963; Heimbürger, 1968; Einspahr and Winton, 1976). Recently, the whole-genome sequence of the first tree species, black cottonwood (*P. trichocarpa*) was reported (Tuskan *et al.*, 2006). The genome size of poplars is estimated to be little less than 500 Mbp (mega base pairs). By integrating shot-gun sequence assembly with BAC (bacterial artificial chromosome) fingerprinting and genetic mapping, the whole poplar genome was assembled. Strong evidence of whole-genome duplication, as is common among diverse members of the Salicaceae family, was also observed. About 45 000 genes appear to be present in the poplar genome.

1.7 Molecular Genetics of Poplars

A systematic approach of using modern molecular genetic techniques to associate economically important traits with molecular markers located on the poplar genome map was initiated relatively recently (Bradshaw *et al.*, 1994). By taking advantage of the success of interspecific hybridization in poplars, most of the genome mapping studies focused on hybrids that also showed hybrid vigor for growth and had been planted on a commercial scale. Because most of the poplars are diploid with $2n = 38$, F_1 hybrids are fertile and can lead to segregating F_2 progenies that are used for tagging important traits. Ease of vegetative propagation allows further selection of useful clones by reducing the time required to transit from hybridization to commercial production. In addition, ease of clonal propagation also allows side-by-side comparison of performance of parents and their F_1 and F_2 progenies in replicated clonal trials. The physical size of the *Populus* genome is about 500 Mbp and is distributed on 19 chromosomes, giving a combined genetic length of 2400–2800 cM (centimorgans; Bradshaw, 1996). Thus, an average correspondence of physical to genetic lengths of poplars is about 200 kb cM^{-1} , which is similar to that found in *Arabidopsis*. Also, the rich information resources for poplars from a variety of subdisciplines of plant sciences such as physiology, anatomy, biochemistry, genetics, molecular biology, ecology, and pathology have made poplar a very attractive model system for tree biologists (Taylor, 2002). The main traits of interest are stem volume, stem form, crown geometry, spring bud burst, climatic adaptation, disease resistance, wood quality, and wood production (Bradshaw *et al.*, 1994; Bradshaw, 1996).

The earliest poplar genetic map was developed by Liu and Fournier (1993) using an intraspecific cross in *P. tremuloides* employing allozymes and restriction fragment length polymorphisms (RFLPs). However, most of the recent efforts have involved interspecific hybrid poplars (e.g., Bradshaw *et al.*, 1994; Cervera *et al.*, 1997). Most of the quantitative trait loci (QTL) mapping efforts in poplars have focused on a single three-generation pedigree developed from a female black cottonwood (*P. trichocarpa*) clone 93-968 from Washington State and eastern cottonwood

(*P. deltoides*) clone ILL-129 from Illinois. These two trees were crossed in 1981 giving rise to F_1 family 53. In 1988, two of the F_1 hybrids (53-246 and 53-242) were sibmated to generate F_2 family 331. These three-generation mapping pedigrees are maintained as clonal materials by cutting new growth to ground each winter in order to produce multiple sprouts. A genome map developed from F_2 family 331 consists of 250 RFLP markers and ~100 random amplified polymorphic DNA (RAPD) markers covering $2/3$ of the 2600 cM length of the poplar genome. This map has been used to localize QTLs for yield, disease resistance, stem growth, leaf morphology, and sylleptic branch proliferations (Taylor, 2002). (Sylleptic branches are produced directly from axillary buds in response to water, light, and nutrients and contribute to fixed carbon stored in stems.) Additional poplar genome maps have been developed including a Belgian cross between *P. trichocarpa* and *P. nigra* or *P. deltoides* (Cervera *et al.*, 2001) and a French cross between *P. nigra* and *P. deltoides* (Cervera *et al.*, 1997). Wu *et al.* (2000) have also developed a new amplified fragment length polymorphism (AFLP) marker-based map in *P. deltoides*. Additional studies are in progress to map QTLs for leaf rust resistance as reviewed by Taylor (2002). Recently, Cervera *et al.* (2005) have used AFLP markers for discerning relationships among various poplar species and their hybrids.

The problems involved in using traditional breeding for poplar improvement include their undomesticated nature, long generation intervals, late sexual maturity, large physical size, strict outcrossing mating system, lack of inbreeding lines, lack of natural or induced mutant lines, polygenic inheritance of economically important traits (this is common with many other crop plants), and the late start of overall research efforts in this direction (Bradshaw *et al.*, 2000). It is hoped that transformation techniques may mitigate some of the disadvantages of working with this system. In contrast to the decade required for completing one cycle of traditional crossing and selection, genetic engineering can reduce this time between six months and a year. Additionally, genetic engineering may be able to uncover the recessive mutations that normally cannot be recovered from outcrossing. Molecular techniques like RNA interference (RNAi) or antisense suppression are

likely to knock out all copies of a gene, and thus provide a glimpse into the functionalities of that gene. Finally, the process of domestication can hopefully be compressed into decades from the usual centuries using these techniques (Bradshaw *et al.*, 2000).

2. POPLAR TRANSFORMATION

2.1 An Overview of Poplar Transformation

All transformation methods, such as biolistic gun (McCown *et al.*, 1991; Devantier *et al.*, 1993), electroporation (Chupeau *et al.*, 1994), and *Agrobacterium*-mediated methods have been successfully used in poplars (Confalonieri *et al.*, 2003). However, the majority of researchers have chosen *Agrobacterium*-mediated transformation as the preferred method in their studies. Table 3 lists some poplar species in which transformation systems have been established.

Populus was the first woody plant genus that was genetically manipulated. In 1986, the first *Populus* transformation was reported in hybrid poplar (*P. trichocarpa* × *P. deltoides*) using two *Agrobacterium* strains (Parsons *et al.*, 1986). The *Agrobacterium*-mediated method of gene transformation has since been successfully employed in many *Populus* species. However, most

of the successful transformations have been limited to the section *Populus* (aspen type) (Han *et al.*, 2000). Transformation reports of *Populus* species belonging to the section *Aigeiros* (cottonwood type) and *Tacamahaca* (balsam poplar type) are not common. However, Han *et al.* (2000) developed an effective transformation system for a variety of cottonwood hybrids. Recently, Ma *et al.* (2004) reported a transformation protocol for the *P. trichocarpa* clone Nisqually-1, notable for having been the clone used to complete the *Populus* genome sequencing project (Tuskan *et al.*, 2006).

Here, we will discuss some of the important factors that affect the ability to transform various poplar species.

2.1.1 Explants

In poplars, the efficiency of transformation is affected by the physiological condition of the explants, which in turn is affected by the environmental and growing conditions of the mother plants. Mature lignified explants with high phenolics are difficult to regenerate (Civinova and Sladky, 1990). In aspen, young leaf discs are most amenable for regeneration and transformation as compared to older leaf discs. Han *et al.* (2000) compared the rate of callus production and shoot

induction using *in vitro*-grown and growth room-grown explants of stem and leaf. The rate of callus and shoot production was significantly lower in *in vitro*-derived stem and leaf explants as compared to growthroom-derived explants in the black cottonwood hybrids that were tested. *Populus* explants commonly preferred for transformation are taken from *in vitro*-grown plants because they need no additional surface sterilization and have high regeneration capacity (Civinova and Sladky, 1990). The transformation methods used in various poplar species and their regeneration efficiency are dependent on the selected genotype. The same transformation method and growth media may not always work well with other genotypes of the same species. Several studies have shown that significant variations exist among the poplar genotypes (DeBlock, 1990; Riemenschneider, 1990; Confalonieri *et al.*, 1994). Various genotypes of the *Populus* section responded differently to *Agrobacterium tumefaciens* infection (Nesme *et al.*, 1987). In *P. deltoides*, four selected clones regenerated significantly better than 14 other clones examined (Coleman and Ernst, 1990). Transformation has been achieved using various explants, such as leaf discs, apices, petioles, internodes, and stems. The best explant for transformation use depends on the poplar species used, its genotype and its susceptibility to *A. tumefaciens* infection. In cottonwood hybrids, stem and petiole explants were shown to produce more calli and regenerate more shoots than leaf explants (Han *et al.*, 2000). Also, the specific type of preculture media on which the explants were grown influences the subsequent transformation efficiency. Cottonwood hybrid internode explants precultured on BA (benzyladenine; 10 μ M) showed increased shoot production as opposed to those precultured on TDZ (thidiazuron; 0.1 μ M) and zeatin (5 μ M), which led to decreased shoot production. For *P. deltoides*, preculture on auxin-supplemented media improved competence for shoot regeneration (Coleman and Ernst, 1990).

2.1.2 *Agrobacterium* strains and culture induction

Different plants (genotypes and species) exhibit varying susceptibility to *A. tumefaciens* infection.

Therefore, choosing the appropriate *Agrobacterium* strain is very important for the success of the transformation experiment, especially for recalcitrant species. Tree species exhibit better infection rates with nopaline strains of *A. tumefaciens* than with octopine strains (Ahuja, 1987). Earlier, Fillatti *et al.* (1987b) and Pythoud *et al.* (1987) reported that transformation of poplars with octopine strains such as LBA4404 was not successful. For *P. nigra* leaf disc explants, the C58 strain was more virulent as compared to the Ach5 and A281 strains (Confalonieri *et al.*, 1994). The effect of *Agrobacterium* strains on poplar transformation rates has also been studied in the highly susceptible *Populus* section clone-INRA-717-184 (*P. tremula* \times *P. cuba*) where the *Agrobacterium* strains used did not significantly affect the rate of transfer DNA (T-DNA) transfer. However, in *Aigeiros* section clones 24-305 and 184-402, the EHA-105 strain of *Agrobacterium* produced a significant increase in the rate of T-DNA transfer compared to the C58 and LBA4404 strains (Han *et al.*, 2000). Acetosyringone is also known to induce the *Vir* genes in *Agrobacterium* during plant infection and is, therefore, commonly used in transformation of monocots (rice, wheat, maize), which are less susceptible to *Agrobacterium* infection. In several black cottonwood clones, the use of acetosyringone in *Agrobacterium* induction also increased the efficiency of transformation (Confalonieri *et al.*, 1995).

2.1.3 Co-cultivation

Optimum concentration of *Agrobacterium* is required for efficient transformation. Incubation of high concentrations of *Agrobacterium* on poplar explants for a long period generally results in necrosis of the explants. In poplars, co-cultivation of stem explants with approximately 5×10^8 cells/ml of *Agrobacterium* caused necrosis after 2 days of co-cultivation. Co-cultivation of *P. nigra* explants with *Agrobacterium* at a concentration of 7×10^8 cell/ml resulted in improved transformation efficiency based on GUS (β -glucuronidase) expression analysis (Confalonieri *et al.*, 1994). Transformation efficiency is also greatly influenced by co-cultivation conditions, such as the nature of media (solid or liquid), medium composition, light or dark conditions during treatment, and

the number of days of incubation (Mathis and Hinchey, 1994). Transformation efficiency of *P. nigra* was improved significantly by co-cultivating explants for 48 h as compared to 24 h of co-cultivation (Confalonieri *et al.*, 1994). In short, careful monitoring of the entire transformation protocol is essential for the successful outcome of transformation of poplars. Excellent reviews on poplar transformations have been published in the past and can be consulted for the topics not covered here (e.g., Rishi *et al.*, 2001; Bhalerao *et al.*, 2003; Confalonieri *et al.*, 2003; Nehra *et al.*, 2005). Below we discuss some examples of commercially important and environmentally beneficial traits for which poplars have been engineered.

2.2 Genetic Engineering of Poplars for Improved Lignin Production

The removal of lignin from wood for paper making is a chemical- and energy-intensive and environmentally polluting process. The reaction rate of lignin degradation during chemical pulping of angiosperm species is inversely related to lignin content, but directly proportional to the quantity of the syringyl content in lignin (Boerjan *et al.*, 2003). Thus, both lignin quantity and structural composition (i.e., the syringyl-to-guaiacyl (S/G) monolignol ratio), affect pulping efficiency and represent two significant traits targeted in forest tree improvement programs. Unlike agronomic crops, such as maize and sorghum, where natural mutants deficient in enzymes of the lignin biosynthetic pathway have been identified, lignin-mutant trees are rare. To date, only one lignin-mutant tree (i.e., loblolly pine clone 7-56), deficient in cinnamyl alcohol dehydrogenase (CAD), has been identified (MacKay *et al.*, 1997; Figure 2). Genetic engineering of pulpwood species with altered lignification is, therefore, regarded as a promising technology for producing raw materials with improved pulping and bleaching characteristics. Largely because of its economic relevance, the lignin biosynthetic pathway has been investigated for nearly four decades. Thanks to the emerging molecular, genomics and reverse genetics tools, several aspects of the monolignol biosynthetic pathway have been substantially revised, and readers are referred to several excellent recent reviews for an in-depth treatment

(Anterola and Lewis, 2002; Boerjan *et al.*, 2003; Rogers and Campbell, 2004). Here, we focus on the biotechnological applications of lignin modification in *Populus* because it is a fast-growing pulpwood species widely planted across the northern hemisphere.

As was the case for herbaceous model species (e.g., tobacco), *COMT* (caffeate O-methyltransferase) and *CAD* were among the first genes targeted for transgenic manipulation of lignin in *Populus* (VanDoorsselaere *et al.*, 1995; Baucher *et al.*, 1996; Tsai *et al.*, 1998; Jouanin *et al.*, 2000; Figure 2). Mutations in these two genes are the cause of reduced lignin content, altered lignin structure, and discolored vasculature in the brown midrib (*bm*) phenotypes of maize (*Zea mays* L.) and sorghum (*Sorghum bicolor* L.) (Vignols *et al.*, 1995; Halpin *et al.*, 1998). In *Populus*, however, lignin content was not reduced by transgenic down-regulation of *COMT* or *CAD*, except in a severe case where *COMT* activity was essentially eliminated, and lignin content was reduced by 17% (Jouanin *et al.*, 2000). Suppression of *COMT* decreased syringyl (S) and increased guaiacyl (G) lignin accumulation in the stem wood (VanDoorsselaere *et al.*, 1995; Tsai *et al.*, 1998; Jouanin *et al.*, 2000). In addition, increased levels of coniferyl aldehyde and incorporation of an abnormal, 5-hydroxyguaiacyl unit into the xylem were observed (VanDoorsselaere *et al.*, 1995; Tsai *et al.*, 1998; Jouanin *et al.*, 2000; Ralph *et al.*, 2001). In the case of *CAD*-deficient transgenic poplars, the lignin S/G ratio remained essentially unchanged, but there was an increase in the incorporation of both coniferyl and sinapyl aldehydes into the lignin (Baucher *et al.*, 1996; Ralph *et al.*, 2001). Wood discoloration reminiscent of the forage *bm* phenotype was also observed in the transgenic trees, but with variations. Wood of transgenic *CAD* plants showed a distinctive red color, while wood color of transgenic *COMT* trees ranged from pale rose to red brown, depending on the means of gene suppression (i.e., antisense vs. sense silencing) (VanDoorsselaere *et al.*, 1995; Tsai *et al.*, 1998; Jouanin *et al.*, 2000).

Lignin reduction in transgenic *Populus* was first achieved by down-regulating 4-coumarate: CoA ligase (4CL), which controls the step at which hydroxycinnamic acids are converted into high-energy hydroxycinnamoyl-CoA intermediates (Hu

Figure 2 The lignin biosynthetic pathway in plants

et al., 1998, 1999; Li *et al.*, 2003). Substantial reductions of stem wood lignin ($\geq 40\%$) were attained in some lines, with a concomitant increase in cellulose content, resulting in a doubling of the cellulose-to-lignin ratio from ~ 2 in wild type to $\geq \sim 4$ in these transgenics (Hu *et al.*, 1999; Li *et al.*, 2003). Unlike CAD- and COMT-suppressed plants, the lignin S/G ratio was not significantly altered in 4CL-down-regulated aspen. This is consistent with 4CL's restricted involvement at an early stage of lignin synthesis, prior to divergence of guaiacyl and syringyl monolignol biosynthesis (Figure 2). The xylem of 4CL-reduced plants displayed a reddish color intermediate to the colors

observed in CAD-deficient and COMT-deficient poplar/aspen.

Successful lignin reduction has also been reported in transgenic poplars with down-regulated *CCoAOMT* (caffeoyl-coenzyme A O-methyltransferase) and *CCR* (cinnamoyl-coenzyme A reductase; Boerjan *et al.*, 2003) genes. In *CCoAOMT*-suppressed plants, the levels of both G and S monolignols were reduced, but the effect was more pronounced for G lignin, resulting in a slightly increased S/G ratio in the stem wood (Meyermans *et al.*, 2000). Accompanying the lignin alteration in the xylem was an increase of soluble phenolics, particularly the β -D-glucosides

of caffeic acid, vanillic acid, and sinapic acid (Meyermans *et al.*, 2000). Elevated levels of free and wall-bound *p*-hydroxybenzoate were also reported in two independent studies (Meyermans *et al.*, 2000; Zhong *et al.*, 2000). In both cases, a red-brown color was observed in the transgenic wood, although the exact chemical basis of the discoloration remains to be identified.

Increased S lignin content (or S/G ratio) has been achieved in *Populus* by overexpressing *F5H* (ferulate 5-hydroxylase), also known as *CAlD5H* (coniferaldehyde 5-hydroxylase), which encodes a P450 enzyme that catalyzes the conversion of coniferaldehyde to 5-hydroxyconiferaldehyde (Humphreys *et al.*, 1999; Osakabe *et al.*, 1999; Franke *et al.*, 2000; Li *et al.*, 2003). Transgenic aspen showed up to a threefold increase in xylem *CAlD5H* activity, and up to 2.5-fold increase in the S/G ratio of stem wood (Li *et al.*, 2003). Lignin content, on the other hand, was not affected (Li *et al.*, 2003). Co-transformation with antisense 4CL and sense *CAlD5H* constructs led to a simultaneous modification of lignin content and composition (Li *et al.*, 2003), a significant advance toward the biotechnology promise of a more pulp-friendly raw material. Co-transformation can accelerate the genetic engineering and evaluation of multiple traits in tree species, and appears to compare very favorably with other gene stacking or retransformation approaches (Halpin, 2005).

Herbaceous species, such as tobacco, *Arabidopsis*, alfalfa, and maize, have been instrumental in elucidating the function of many of the lignin biosynthetic pathway genes. However, available data from herbaceous models and poplar systems have revealed several interesting distinctions. For instance, overexpression of *F5H* under control of the constitutive cauliflower mosaic virus (CaMV) 35S promoter was ineffective in promoting S lignin accumulation in transgenic tobacco stems (Franke *et al.*, 2000), but was effective in transgenic aspen (Tsai *et al.*, 2004). Furthermore, some genes that were successfully targeted for lignin reduction in herbaceous systems could not be manipulated to reduce lignin content in poplars. Examples are COMT-deficient transgenic tobacco (Ni *et al.*, 1994), alfalfa (Guo *et al.*, 2001), and maize (Piquemal *et al.*, 2002), *bm* COMT and CAD mutants of maize and sorghum (Chabbert *et al.*, 1994; Vignols *et al.*, 1995;

Halpin *et al.*, 1998), and *F5H*-overexpressing transgenic tobacco (Franke *et al.*, 2000). Lignin degradability also differed between transgenic maize and poplar with similarly reduced COMT activity: COMT suppression had an adverse effect on pulping performance of transgenic poplar (Pilate *et al.*, 2002), while COMT-reduced maize showed an enhanced *in vitro* digestibility (Piquemal *et al.*, 2002). In both cases, the lignin structure was similarly altered, but, as described above, transgenic maize also had a reduced lignin content which may account for the reported discrepancy in end-use benefit. The results also suggest that positive trait improvement brought about by lignin reduction may offset the negative effect of decreased S/G ratio to have a net positive impact on lignin degradation.

As a corollary, these observations also indicate that some aspects of cell wall formation and lignin biosynthesis in woody perennials are not well modeled using herbaceous species. Analysis of the recently completed poplar genome sequence reveals an expansion in the number of genes involved in phenylpropanoid metabolism and lignin biosynthesis as compared to *Arabidopsis* (Tsai *et al.*, 2006; Tuskan *et al.*, 2006). However, only a small fraction of these genes has been functionally characterized in transgenic *Populus* (Table 4).

Several phenylpropanoid gene families in poplars contain structurally and spatiotemporally distinct isoforms that are differentially associated with lignin and nonlignin phenolic biosynthesis. Examples include the phenylalanine ammonia-lyase (PAL; Kao *et al.*, 2002), 4CL (Hu *et al.*, 1998; Harding *et al.*, 2002), and cinnamate 4-hydroxylase (C4H; Lu *et al.*, 2006) families. Differential expression among members of the HCT (hydroxycinnamoyl-CoA quinate/shikimate hydroxycinnamoyltransferase) family in lignifying versus green/soft tissues of poplar has also been reported (Tsai *et al.*, 2006). Similar expression patterns of the C3H (coumarate 3-hydroxylase) family can also be inferred from the large-scale *Populus* EST (expressed sequence tags) dataset (Sterky *et al.*, 2004). Targeting xylem-specific isoforms of the PAL, C4H, C3H, and HCT families for genetic manipulation should provide further insight into the lignin biosynthetic pathway, and may yield new strategies for transgenic manipulation of lignin.

^(a)Number of genes associated with lignin biosynthesis, based on expression analysis of *Arabidopsis* (Raes *et al.*, 2003) and *Populus* (Sterky *et al.*, 2004; Tsai *et al.*, 2006) genes, or according to the original literature cited in the text

^(b)Number of genes associated with lignin biosynthesis based on characterization of mutant or transgenic plants

^(c)Sinapyl alcohol dehydrogenase (SAD) shown to be involved in S lignin biosynthesis of *Populus* (Li *et al.*, 2001) is included, but its involvement in *Arabidopsis* lignification has not been supported (Sibout *et al.*, 2005). Note two CAD genes are present in *Arabidopsis* versus one in *Populus*

With regard to quantitative lignin modification, a common feature among the three enzymatic steps successfully targeted for lignin reduction in poplar (i.e., 4CL, CCoAOMT and CCR), is their production and utilization of high-energy hydroxycinnamoyl-CoA esters (Figure 2). By the same measure, this “hot spot” for lignin reduction may also include HCT, as boxed in Figure 2, and possibly C3H for its putative role in conversion of *p*-coumaroyl-CoA to caffeoyl-CoA (Wang *et al.*, 1997). Transgenic down-regulation of xylem-specific *HCT* and *C3H* in poplar will help substantiate this hypothesis, as well as help clarify *C3H* function. *F5H* overexpression appears to be the only approach to significantly augment S lignin production. It should be noted that among the many lignin pathway genes reportedly targeted for transgenic modification to date (Table 4), *F5H* overexpression represents the only case in which the sense transgene did not trigger co-suppression or gene silencing (Li *et al.*, 2003). In aspen, *F5H* overexpression was achieved by using either a xylem-specific aspen *4CL1* promoter (Hu *et al.*, 1998; Harding *et al.*, 2002) or a constitutive CaMV 35S promoter, and either a homologous (aspen) or a heterologous (sweetgum, Osakabe *et al.*, 1999) transgene, each producing similar efficacy (Tsai *et al.*, 2004). Because sense transgene-mediated gene silencing is dependent, at least in part, on the level of endogenous expression (e.g., Vaucheret *et al.*, 1998), endogenous *F5H* transcripts may have a very short half-life. The inability to overexpress other lignin pathway genes may account for the general lack of transgenic phenotypes with increased lignin deposition in the studies cited above. Conversely, increased or ectopic deposition of lignin in transgenic plants has only been reported by manipulation of transcription factors (Newman *et al.*, 2004; Goicoechea *et al.*, 2005; Sanchez *et al.*, 2006).

In closing, since the first report of transgenic poplar with modified lignin (VanDoorselaere *et al.*, 1995), the past 12 years have witnessed significant progress in lignin biotechnology for pulpwood species. Traits of commercial relevance (e.g., reduced lignin content and/or more reactive lignin structure), have been successfully introduced into elite *Populus* clones, and their biological and ecological performance have been evaluated in the laboratory and in field settings. For instance, insect herbivory on lignin-reduced aspen has been examined with no direct link apparent

between lignin reduction and laboratory feeding performance of gypsy moth larvae and forest tent caterpillars (Brodeur-Campbell *et al.*, 2006). Elsewhere, a four-year field evaluation of CAD-deficient transgenic poplar at two European sites showed improved Kraft pulping performance, with higher pulp yields and less cellulose degradation as compared to the control (Pilate *et al.*, 2002). Importantly, interactions with leaf insects, pathogens, and soil microbes were not altered (Pilate *et al.*, 2002). These examples point to real promise in reducing the burden of lignin removal to the pulp and paper industry. Commercial-scale use of these trees would translate into significant monetary savings and environmental benefits due to reduced chemical and energy inputs, and reduced outputs of pollutants associated with pulping.

2.3 Transgenic Modification of Gibberellin (GA) Biosynthesis and Signaling

Bioactive forms of GA control diverse plant developmental processes, including seed germination, flower initiation, fruit development, stem elongation, leaf expansion, and trichome development (Davies, 1995). Substantial efforts are underway in a variety of plant species to understand the molecular mechanisms of many of these GA-mediated processes (Olszewski *et al.*, 2002).

Research in the last several years has demonstrated that deficiencies in GA levels or perturbations in the GA signaling pathway are a powerful means to control plant size (Peng *et al.*, 1999; Spielmeier *et al.*, 2002). Low levels of bioactive GA and signaling lead to dwarfism, while conversely higher levels of several bioactive GA forms and increased signaling induce rapid shoot elongation and larger organ size (Davies, 1995). Therefore, transgenic alterations of GA metabolism and/or signal transduction are being viewed as logical approaches for altering growth patterns in trees.

A number of studies substantiate the expectation that based on herbaceous plant studies; GA-related genes will be a powerful means to control the stature and development of woody plants. Early reports considering GAs in woody plants indicated that they stimulate cambium division, whereas auxin is needed for lignification (Wareing,

1958). Using the *Arabidopsis* gene that encodes the GA 20-oxidase enzyme, which catalyzes one of the last steps in GA biosynthesis, GA-overproducing transgenic poplar trees were produced. Transgenic plants displayed enhanced overall growth, as well as longer wood fibers compared to wild-type (WT) plants (Eriksson *et al.*, 2000). Overexpression of a poplar GA 3-oxidase had no effect on transgenic poplar growth and development, suggesting that GA 20-oxidase controls the flux of bioactive GAs in the pathway, a conclusion supported by studies in other annual plants (Israelsson *et al.*, 2004). Thus, it appears that GA can regulate cambium division and some aspects of the differentiation of newly formed vascular initials, and could be an important means of modifying growth and wood quality—critical economic traits in trees.

In trees, dwarfism can be an important mitigation and production trait. The mitigation value is largely considered in the context of a biosafety, limiting spread of transgenes in wild populations (Danielle, 2002). Because competition for light in trees is essential for their survival, slow-growing dwarfing varieties will have a substantial disadvantage compared to their wild relatives. Therefore, these kinds of trees would likely be eliminated early, with little chance for reproduction. However, in an intensively managed plantation where trees are cultured as wood fiber crops, semi-dwarfism may bring about beneficial alterations in tree growth patterns (Bradshaw *et al.*, 2000). For example, domesticated trees that are substantially shorter and stouter may produce less reaction wood (which degrades wood and pulp quality) and give a higher harvest index. Such trees will also have improved harvesting/handling efficiencies and enable greater unit-area fiber yields. Crowns of dwarfed trees will likely be narrower, allowing for a greater number of stems per unit area. Several studies have reported successful induction of dwarfism using transgenic modifications of GA-related genes. Overexpression of a poplar and bean GA 2-oxidase causes dwarfism via reduction in shoot elongation (Busov *et al.*, 2003). GA 2-oxidase is the last step in GA metabolism and is involved in conversion of the bioactive GA_{1/4} into their inactive forms GA_{8/34}. High expression of the gene is associated with increased deactivation of the bioactive GAs that consequently led to decreased elongation and dwarfism. Dwarfism can be rescued by application of a bioactive synthetic form of

the hormone (GA₃) that cannot be catabolized by GA 2-oxidase. Alternatively, dwarfism was successfully induced by overexpression of DELLA (D = Aspartic acid, E = Glutamic acid, L = Leucine, A = Alanine) proteins—strong repressors of GA signaling. DELLA proteins belong to the GRAS family of transcription factors but, in contrast to all other members of this family, have a conserved DELLA domain in the N-terminus that mediates GA-induced sensitivity to photolytic degradation. Complete truncation or nonsynonymous substitution in this domain causes a strong dominant dwarfing effect not only in *Arabidopsis* but also in a number of other species. Similarly, overexpression of DELLA proteins with a mutated DELLA domain induced a strong dwarfing effect in *Populus*. In addition, dwarfed poplars displayed increased root production under *in vitro* conditions and changes in secondary metabolism associated with shifts to storage and defense compounds (Busov *et al.*, 2006). Along with GA, genes involved in the biosynthesis of other plant hormones have also been identified and manipulated. An excellent review by Confalonieri *et al.* (2003) covers those aspects as well as altered growth characteristics of transgenic poplars (e.g., Gallardo *et al.*, 1999). In addition, a number of recent reviews discuss the general applications of genetic-engineering trees in forest biotechnology (e.g., Mann and Plummer, 2002; Merkle and Nairn, 2005). These papers also discuss various aspects of growth alterations in trees.

2.4 Manipulation of Reproductive Development in Poplars

The ability to control flowering in forest trees is desirable for many reasons. The multiple-year juvenile or nonflowering phase of trees is a major impediment to tree improvement and, thus, one goal is the ability to routinely induce flowering in juvenile trees in order to speed breeding (Bhalerao *et al.*, 2003). Prevention of flowering or sterility is desired for forest trees growing in production plantations in order to provide genetic containment (Brunner *et al.*, 2007) and to route more photosynthate into biomass production and not into reproduction (Bradshaw and Strauss, 2001; Ragauskas *et al.*, 2006). Achieving these competing outcomes—inducible early flowering

and suppression of flowering over a multiple-year rotation—is technically challenging, but not an insurmountable paradox. Ideally, a system for transient induction of flowering that can easily be applied to an infinite number of genotypes is desired to advance breeding. In contrast, suppression of flowering should be a stable trait that is introduced into elite clones as the final step in tree improvement.

Various environmental and endogenous signals regulate the transition to flowering via multiple interacting genetic pathways that have been most extensively deciphered in *Arabidopsis* (Boss *et al.*, 2004; He and Amasino, 2005; Ausin *et al.*, 2005). Numerous studies have also identified genes controlling the initiation and differentiation of floral organs in *Arabidopsis* and other annual plants, such as snapdragon and petunia (Jack, 2004). Most studies of genes involved in flowering in trees have dealt with homologs of genes known to control various stages of flowering in *Arabidopsis*. Gene expression studies and heterologous constitutive expression of these tree genes in *Arabidopsis* and tobacco have indicated broad conservation of function in most cases. Studies of flowering gene function in trees have been relatively rare, but the number of analyses completed in transgenic poplar is increasing and these have revealed significant differences in gene function as compared to *Arabidopsis*.

Several *Arabidopsis* genes induce early flowering when constitutively expressed in *Arabidopsis*, but do not accelerate flowering when expressed in poplar (Brunner and Nilsson, 2004; Strauss *et al.*, 2004). Overexpression of the floral meristem identity gene *LEAFY* did induce precocious flowering in some male poplar genotypes, but flowers were abnormal and not fertile (Weigel and Nilsson, 1999; Rottmann *et al.*, 2000). In contrast, constitutive expression of *PtFT1*, a poplar homolog of the *Arabidopsis* flowering time gene *FT*, induced normal flowers in both male and female genotypes in only a few months (Bohlenius *et al.*, 2006). The identification of *PtFT1* as a potent inducer of functional flowering is an important step toward a system of accelerated flowering in order to advance breeding. The study by Bohlenius *et al.* (2006) also revealed differences between poplar and *Arabidopsis*. Whereas *FT* only affects flowering time in *Arabidopsis*, *PtFT* controls both flowering and the short day-induced

growth cessation that occurs in fall as trees prepare for winter dormancy. This result raises the possibility that genes affecting only the flowering in *Arabidopsis* could have additional functions in poplar that reflect the difference between the rapid-cycling annual growth habit of *Arabidopsis* and poplar's perennial woody growth habit. This also indicates that manipulating genes for flowering control in trees may have undesired additional effects on vegetative growth. As described above, induction of flowering should be inducible and transient, which would avoid secondary effects on vegetative growth. However, vegetative effects may be more problematic for engineering sterility.

Even with a strong inducer of flowering in poplar identified, developing an efficient system for “flowering on demand” remains problematic. The alcohol-inducible promoter system is effective in poplar (Filichkin *et al.*, 2006a), and other chemical- or heat shock-inducible promoter systems may also work well in poplar. Perhaps a greater obstacle is developing a simple, rapid method to deliver a transgene to any genotype. *FT* is transcribed in leaves and the *FT* protein is transported to the shoot meristem, where it acts to promote flowering, and transient expression of *FT* mRNA in leaves is sufficient for flowering (Corbesier *et al.*, 2007; Jaeger and Wigge, 2007). Thus, for *FT*-mediated induction of flowering, grafting or an *Agrobacterium*-mediated transient expression system (Johanson and Carrington, 2001), whereby *Agrobacterium* transformed with a *PtFT1* transgene is infiltrated into leaves on an intact plant, might be an effective option. Another approach to induce flowering is to suppress genes that repress flowering, though this has yet shown to be effective in poplar. In this case, virus-induced gene silencing (VIGS) vectors (Burch-Smith *et al.*, 2004) might be an efficient, transient method for inducing flowering in any genotype in a greenhouse. A VIGS vector has recently been developed for poplar (Naylor *et al.*, 2005).

Introduction of genes that cause reproductive sterility or prevent flowering are generally viewed as an enabling technology for commercial use of transgenic forest trees. Dispersal of pollen and seed from transgenic, exotic, or intensively bred forest plantations may cause significant ecological impacts on wild or managed ecosystems. Although genetic containment is also a concern

for some agricultural crops in some locations (Chapman and Burke, 2006; Lee and Natesan, 2006), concerns over transgene escape are greater for forest plantations. This concern is based on the complexity and scale of gene flow that results from the large size and longevity of trees and the frequent proximity of plantations to wild relatives (Williams, 2005). The genes and strategies for engineering reproductive sterility in trees as well as related risk assessment have recently been comprehensively reviewed (Brunner *et al.*, 2007). Here, we will highlight a few of the options available in order to illustrate both the potential and the difficulties of developing genetic containment methods for trees.

Potentially, reproductive development could be blocked at any stage—from the transition to flowering to the final stages of gamete development. Although the functions of only a few flowering genes have been directly characterized in poplar (e.g., Rottmann *et al.*, 2000; Bohlenius *et al.*, 2006), poplar homologs of most of the *Arabidopsis* genes involved in flowering have been identified in (e.g., Brunner and Nilsson, 2004). Many of these genes have expression patterns in poplar that indicate functional conservation (e.g., Rottmann *et al.*, 2000). Blocking the transition to flowering is desired, because this would completely avoid any investment in floral formation, allowing all resources to be directed toward vegetative development. One of the difficulties in demonstrating an effective, stable sterility system in trees is that large trees need to be monitored for many years. Therefore, absence of flowering has the additional advantage of being simpler to confirm than sterility methods that allow formation of floral structures that then need to be examined microscopically to verify sterility. However, prevention of flowering may not be desirable in all cases, such as when a plantation provides important habitat for birds or insects that feed on flower parts. Due to the difficulties in demonstrating a robust sterility system in trees and the genetic redundancy in the flowering control (Irish and Litt, 2005), redundant sterility systems that target different stages of flowering or act via multiple mechanisms might be the best approach to ensure a high level of gene confinement.

Approaches for engineering bisexual sterility fall into three categories: (1) floral ablation, whereby

a floral specific promoter directs expression of a cytotoxin; (2) repression of the transition to flowering by modifying the expression of genes that repress this developmental phase change; and (3) suppression of genes necessary for reproductive development at the DNA, RNA, or protein levels. All have advantages and disadvantages (see Brunner *et al.*, 2007 for a comprehensive description). For example, the ablation approach avoids the complication of genetic redundancy, but low levels of transgene expression in vegetative tissues can have detrimental effects on growth that may not be apparent under greenhouse conditions but appear as a cumulative effect in the field. RNA-mediated gene suppression, also called RNAi, is currently the most widely used method to inhibit gene activity, but it does not completely suppress a gene's expression. Recent advances in targeted gene mutagenesis and replacement using the yeast *RAD54* gene (Shaked *et al.*, 2005) or zinc-finger nucleases (Lloyd *et al.*, 2005; Wright *et al.*, 2005) may eventually lead to efficient methods for engineering null alleles of reproductive genes in poplar.

The long delay to flowering in poplars (3–6 years on good field sites) has been a major obstacle to demonstrating an effective sterility system in trees. Although an early flowering poplar genotype was identified (Meilan *et al.*, 2004b), its transformation efficiency was low and it did not reliably flower in the greenhouse. Screening sterility transgenes in an inducible *PtFT* background (discussed above) might be useful in some cases, such as an ablation transgene targeting reproductive organs or an RNAi transgene causing abnormal reproductive organ development, but induction of *PtFTI* expression confounds the effects of transgenes designed to prevent flowering. Nonetheless, results to date are encouraging. A cytotoxin directed by the tapetal-specific *TA29* promoter from tobacco dramatically reduced pollen production and a *PTLF*-antisense transgene induced abnormal flowers and reduced fertility in a male poplar clone (Brunner *et al.*, 2007). Additional sterility transgenes that use different mechanisms and target different stages of flowering have been introduced into poplar and are undergoing field evaluation. In addition, the genomic platforms available for poplar are facilitating analysis of the gene networks controlling flowering, which, in turn, will enable selection of genes, promoters, and

strategies for manipulating flowering with greater precision and effectiveness.

2.5 Insertional Mutagenesis Using Transgenic Poplars

Genome-scale T-DNA mutagenized populations represent powerful tools for functional genome exploration in model organisms (Alonso *et al.*, 2003). Such resources are most efficient when a genome sequence is available. In the two species where a full, annotated genome sequence is available (*Arabidopsis* and rice), such resources were developed, and continue to be developed, for specific needs as core tools for functional gene characterization (Alonso *et al.*, 2003; An *et al.*, 2003). Except for a few pilot studies (Busov *et al.*, 2003; Groover *et al.*, 2004), such resources are not available in *Populus* or any other tree species. Perennial woody plants have many developmental differences from annual herbaceous plants such as *Arabidopsis* and rice. These include vegetative dormancy, delayed onset of flowering, extended periods of secondary (woody) growth, and gradual vegetative maturation. Therefore, forward genetic approaches using mutagenized populations are likely to uncover many new types of genes, as well as new functions for already discovered genes.

The advantages of using transgenics mutagenesis approaches in trees have already been reviewed (Busov *et al.*, 2005). Three main approaches emerge as feasible in trees—activation tagging, enhancer/gene traps, and transposon tagging, all of which employ transgenics.

Activation tagging is an insertional mutagenesis approach that produces dominant and semi-dominant mutations that can be identified in T₁ (primary) transgenics, a feature that is extremely important in trees because their long generations and inbreeding intolerance precludes selfing for exposing recessive mutations. Activation tagging uses a special T-DNA vector that randomly inserts in a genome location and contains strong enhancers positioned near the left or right borders (Hayashi *et al.*, 1992; Weigel *et al.*, 2000). The vector, when integrated near a gene, causes its up-regulation by the proximity of the enhancers and a gain-of-function, dominant mutation is produced (Hayashi *et al.*, 1992). Integration position is established by recovering a genomic

sequence flanking the insertion sites by employing either TAIL-PCR (thermal asymmetric interlaced-polymerase chain reaction) (Liu *et al.*, 1995) or plasmid rescue techniques (Weigel *et al.*, 2000). Several genes encoding key *Arabidopsis* developmental regulators have been identified via activation tagging. These include the *histidine kinase* gene, whose overexpression bypasses the need for cytokinin in shoot regeneration (Kakimoto, 1996); the flowering time gene *FT*, whose overexpression causes early flowering in *Arabidopsis* (Kardailsky *et al.*, 1999); and *SUPPRESSOR OF OVEREXPRESSION OF CO1* (*SOCI*), whose overexpression suppressed the late flowering phenotype of plants with functional *FRIGIDA* (*FRI*) and *FLOWERING LOCUS* (*FLC*) alleles (Lee *et al.*, 2000). Because of the utility of this method, a special activation tagged, sequenced-indexed stock center was created for *Arabidopsis* (Ichikawa *et al.*, 2003) and rice (Jeong *et al.*, 2006).

In *Populus*, one activation tagging population of 627 lines was generated and planted in a field trial in western Oregon, USA. The first gene tagged via insertional mutagenesis in any tree came from this pilot population (Busov *et al.*, 2003). The gene encodes a GA 2-oxidase (GA2ox), and the activation resulted in a mutant displaying a distinct dwarf phenotype, dark green foliage, and increased trichome production. Using plasmid rescue, the activation tag was positioned approximately 300 bp up-stream of the translation start site, causing hyperactivation of the gene. Using a variety of approaches, the causal relationship between gene activation and phenotype was demonstrated, verifying the function of the tagged gene. This population is still under active study, and many more tagged genes will likely be discovered (Busov *et al.*, 2005). A new population of approximately 2000 events has been produced, resulting in interesting and useful phenotypes that help elucidate unique aspects of woody perennial biology (S. Reagan, personal communication).

Another transgenic strategy for mutagenesis is based on screening for gene expression by using various reporter genes rather than mutant phenotypes (Springer, 2000). Enhancer trapping employs a T-DNA vector carrying a reporter gene preceded by a minimal promoter that typically contains basal sequences required for

transcription and translation, but are not sufficient to drive expression of the reporter gene. As with activation tagging, the enhancer trap vector is inserted randomly into the genome, and when integrated into or near a gene, the reporter gene is expressed in a pattern that reflects native expression of the proximal gene. To identify the nearby gene, flanking sequences of the vector insertion site are recovered using similar methods as described above for activation tagging. Gene traps are designed and act in a similar fashion. In contrast to enhancer traps, gene traps must integrate into a gene in order to be informative. Because of this special requirement, gene traps are usually less efficient than enhancer traps. This technology has been used in *Populus* to identify genes involved in vascular development and wood formation (Groover *et al.*, 2004). Eight percent of gene-trap lines showed marker gene expression in leaves or stems of tissue-culture-grown plants, which corresponds approximately to the tagging efficiency of this method (Groover *et al.*, 2004). Genes related to wood formation have been discovered and are currently under study. Screens not restricted to woody perennial development were also performed and proved to be productive in characterizing genes that were not identified in model annual plants (Filichkin *et al.*, 2006b). Searches for genes expressed during lateral/adventitious root formation identified several enhancer trap lines showing distinct expression of the reporter gene during lateral root initiation. In one line, the insertion was positioned to a gene encoding a DNA-hook transcription factor (Filichkin *et al.*, 2006b). By fusing the promoter of this gene to the same reporter gene, the expression pattern was recapitulated in *Populus* and *Arabidopsis*. This allowed identification of a promoter that directs transcription exclusively in lateral roots.

Finally, delivery of heterologous maize transposon in transgenic poplars has been used as a third strategy for insertional mutagenesis. Transfer, excision, or reintegration of the maize *Ac* transposon has been reported in *Populus* (Howe *et al.*, 1991; Kumar and Fladung, 2003). Because transposons primarily generate recessive mutations, their usage in *Populus* is limited by the requirement of several rounds of selfing to bring the mutation to a homozygous state, thus exposing the phenotype. Haploid cultures have

been proposed to mitigate this problem (Deutsch *et al.*, 2004).

2.6 Field Trials With Transgenic Poplars

Field trials are essential for examining the phenotypic characteristics and the stability of transgenic plants under wild growing conditions. According to the information available at <http://www.isb.vt.edu/cfdocs/fieldtests1.cfm>, where the Animal and Plant Health Inspection Service (APHIS) compiles data on all US transgenic plant field trials (Notifications and Release Permits), over 11 000 such trials have been conducted in the US since 1987 (Figure 3).

The main phenotypic characteristics being tested in these trials include a variety of agronomic properties, pest resistance traits (viral, bacterial, fungal, and insect resistance); herbicide tolerance; and product quality. Of these trials, 144, carried out by various US universities and private companies, used poplars as an experimental system. In 110 of these trials, the poplar species was not specified, 18 used *P. deltoides*, and 12 used a given variety of hybrid poplar. Some of the universities involved in these trials, were Oregon State University, University of Washington, Mississippi State University, University of Connecticut, New York State University, and Michigan Technological University. Private companies involved in poplar field trials were ArborGen, Mead-Westvaco, Monsanto, and Applied Phytogenetics. The first permission for a transgenic poplar field trial was issued in 1989 to Iowa State University to perform a field test for a marker gene, chloramphenicol acetyl transferase or CAT. Since that time, genes for: herbicide tolerance; insect, bacterial, and fungal resistance; agronomic properties like lignin reduction; and flowering traits, have been tested in transgenic poplars. In Europe, data for over 2000 summary notifications using transgenic plants has been compiled for 28 countries. Countries such as France, the Netherlands, Spain, and the United Kingdom have performed over 200 field trials each during the period 1991–2006 (<http://biotech.jrc.it/deliberate/dbcountries.asp>). Of these, only about 20 deal with transgenic poplars, although each study could include

Figure 3 Transgenic field trials in the United States during 1987–2006

one or more organism (<http://biotech.jrc.it/deliberate/dbplants.asp>).

The data on transgenic poplar field trials from other countries are not readily available. The most noteworthy of those is China's ambitious plan to plant one million transgenic poplar trees carrying the insect resistance gene from *Bacillus thuringiensis* (http://www.chinadaily.com.cn/english/doc/2005-04/01/content_430016.htm). China launched the "Great Green Wall" project in 2001, in which a government-sponsored reforestation project aspires to plant a 2800-mile shelterbelt of genetically engineered (GE) trees around the Gobi desert. Transgenic poplars resistant to insects have been planted in northern China, which typically has little rainfall. Chinese researchers believe that there is little chance for escaped transgenic seeds or sprouts to survive in this hostile climate. Only two poplar clones, Poplar-12 and 741 have been approved and planted on about 200 hectares. This falls far below the Chinese government's target of one million trees. The Institute of Science in Society (ISIS), a British organization highly critical of genetically modified organisms (GMOs), however, has criticized this experiment. By their estimates, over 1 million genetically modified (GM) trees have been planted in this particular experiment and 400 000 more such trees have been planted in other parts of China (<http://www.i-sis.org.uk/GMTGL.php>). The concerns of ISIS range from genetic pollution of forests to the negative social impact of such

large-scale experiments. An article in American Chemical Society's technology newsletter of January 26, 2005, paints a less pessimistic picture. They describe the undertaking as a "grand experiment". Brazil appears to be the next country in following with large-scale GE tree production. Sedjo (2006) recently presented a balanced view of the potential of GE trees to resolve the myriad problems faced by the world's forests. He holds that China has released far less than 1 million GE trees. In other parts of the world, transgenic poplars have been field-tested for a variety of introduced traits including herbicide tolerance, insect resistance, and flowering and stature control. These traits will be discussed in detail in the following sections.

2.6.1 Herbicide tolerance

Fillatti *et al.* (1987a) reported the *Populus* transformation results involving the insertion of an herbicide-tolerance gene derived from *Salmonella typhimurium* (*aroA*). A mutation in this gene resulted in the formation of a 5-enolpyruvyl-3-phosphoshikimate synthase (EPSPS) that was resistant to inhibition by glyphosate, the active ingredient in Roundup® herbicide (Comai *et al.*, 1983). Ectopic expression (*MAS*, mannopine synthase promoter) of this gene yielded surprisingly low levels of herbicide tolerance (Riemenschneider

et al., 1988). This was thought to be the result of low, cytosolic expression of *aroA*. When the same poplar genotype (NC-5339, *Populus alba* × *Populus grandidentata*) was transformed with *aroA* under the control of the CaMV 35S promoter and a chloroplast transit peptide, the resulting plants showed higher levels of glyphosate tolerance (Riemenschneider and Haissig, 1991; Donahue *et al.*, 1994). Although use of the 35S promoter led to higher expression levels than *MAS*, and the transit peptide directed transgene product to the chloroplast, performance of these *aroA*-containing lines (i.e., unique transformation events) still fell short of expectations (Karnosky *et al.*, 1997). After greenhouse spray tests, chlorophyll content in all transgenic lines was inversely correlated to glyphosate concentration, height growth was arrested following herbicide treatment, and only one line retained live leaves six weeks after treatment (Donahue *et al.*, 1994).

Meilan *et al.* (2002b) tested a construct containing two glyphosate-tolerance genes, *CP4* and *GOX*, for its ability to impart glyphosate tolerance in poplar. *CP4* is an alternative form of EPSPS and was cloned from the *A. tumefaciens* strain CP4. Glyphosate has a low affinity for this form of the enzyme. *GOX* is a gene isolated from *Achromobacter* strain LBAA; it encodes glyphosate oxidoreductase, which is an enzyme capable of metabolizing glyphosate. The initial breakdown product of the reaction catalyzed by *GOX* is aminomethylphosphonic acid (AMPA; Barry *et al.*, 1992). Using an *Agrobacterium*-mediated transformation protocol (Leple *et al.*, 1992; Han *et al.*, 2000), Meilan *et al.* (2000) generated transgenic plants in six clones of hybrid poplar (four clones of *P. trichocarpa* × *P. deltoides*, and one clone each of *P. tremula* × *P. alba* and *P. tremula* × *P. tremuloides*).

Ten percent of their transgenic lines showed no foliar damage or reduced growth after being sprayed with Roundup® at concentrations above usual commercial doses. This was hypothesized to be due to *CP4* expression and not that of *GOX*. Many agronomic crops containing both *CP4* and *GOX* became chlorotic in response to glyphosate treatment, likely resulting from the conversion of glyphosate to AMPA.

To test for undesirable effects of *GOX*, they produced 12 additional lines containing only the *CP4* gene. The performance of these lines was

compared to 12 lines produced in the same genotype, into which both *CP4* and *GOX* had been inserted. Growth of the lines containing only *CP4* was significantly better than those containing both genes and they exhibited less damage in response to glyphosate treatment. This was the first report of transgenic poplars exhibiting high levels of glyphosate tolerance when grown under field conditions (Meilan *et al.*, 2002b).

2.6.2 Insect resistance

Insect pests are a major problem for poplar plantation managers. The two main classes are chrysomelid beetles and lepidopteran caterpillars. Both are susceptible to microbial pesticides derived from different strains of *Bacillus thuringiensis* (*Bt*). The products encoded by *Bt* toxin genes have been used safely as microbial pesticides in numerous crops (Carozzi and Koziel, 1997). These toxins are relatively selective insecticides that have very few nontarget effects (James, 1997). Many different *Bt* strains have been identified, each affecting a select group of insects that are usually closely related phylogenetically (Thompson *et al.*, 1995).

The use of GE trees to produce *Bt* toxins is preferable to spray applications for several reasons. First, vegetation, soil, and water surrounding the crop are not exposed to spray drift. Susceptible, nontarget insects in areas adjacent to the transgenic crop would not be exposed, reducing the potential for development of *Bt* resistance. Second, spray applications quickly degrade, persisting on leaves for, at most, a few days (Thompson *et al.*, 1995; James *et al.*, 1999). GE trees, however, can produce the toxin continuously, thereby avoiding sensitivities to application timing and the costs associated with repeated applications. Finally, because transgenic trees produce the toxin within plant tissues, it is possible to target insects residing in the plant, such as wood borers and leaf folders. For some of these pests, no insecticides are available that target the life stage responsible for the damage.

The cottonwood leaf beetle (CLB, *Chrysomela scripta* Fabricius) is the primary insect pest in poplar plantations. It is a multivoltine insect that has a wide distribution and can produce outbreaks causing severe defoliation, particularly in young plantations (Hart *et al.*, 1996). Significant growth

loss has been shown in poplar after two years of simulated leaf beetle defoliation (Reichenbacher *et al.*, 1996). Unlike weed control, which is only needed for the first few years of a poplar rotation, insect control is often repeated during each year of a rotation, making it costly for growers. James *et al.* (1999) have demonstrated that a *Cry3A Bt* toxin is highly effective against the CLB.

A binary vector containing a *Cry3A* gene under the control of the 35S promoter was used to produce 51 insect-resistant lines in four genotypes of *Populus* (16 lines in 24-305 and nine in 189-434, both of which are *P. trichocarpa* × *P. deltoides* triploids; 17 in 50-197, which is a *P. trichocarpa* × *P. deltoides* diploid; and nine in OP-367, a *P. deltoides* × *P. nigra* diploid). The neomycin phosphotransferase II (*NPTII*) gene under the control of the nopaline synthase (*NOS*) promoter was used as a selectable marker. The T-DNA insert was bordered by matrix attachment region (MAR) elements (Allen *et al.*, 1996). The transgenic trees were field tested in eastern Washington State.

This trial relied on insect pressure from the surrounding, commercial stands to evaluate insect resistance. Trees were evaluated for damage seven weeks after planting and again at the end of the growing season. Records on height and basal diameter were taken on all trees immediately after planting, and at the same time as damage ratings were scored. Virtually all of the *Bt* transgenics showed very low feeding damage, whereas the nontransgenic lines sustained significantly higher levels of defoliation. Moreover, in most cases, the mean growth for transgenic lines was greater than that for the nontransgenic controls within each clone (Meilan *et al.*, 2000).

The potential for insects to develop resistance to GE crops is a major concern (DiCosty and Whalon, 1997; James, 1997; Roush and Shelton, 1997). Before insect-resistant transgenics can be commercialized, a resistance management plan must be developed. Many management strategies have been proposed based on prior experiences with pesticide resistance (e.g., Luttrell and Caprio, 1996; Roush, 1997; Gould, 1998; McGaughey *et al.*, 1998). Combining resistance genes (pyramiding or stacking) is one way of reducing the risk of insects becoming resistant to *Bt* gene products (Nwanze *et al.*, 1995; Maredia and Mihm, 1997; Roush, 1997). This

approach has proven to be an effective strategy for resistance management with the cotton bollworm (*Helicoverpa armigera*; Zhao *et al.*, 1997).

To obtain approval from the US Environmental Protection Agency (EPA) to deploy trees containing a gene encoding a *Bt* toxin, additional studies are needed of beetle dispersal, given that natural refugia are effective buffers for preventing the development of resistance (Matten, 1998).

2.6.3 Flowering control

Before GE trees can be commercialized, the APHIS (a division of the USDA) is likely to require a strategy to mitigate the risk of transgene spread and persistence in the environment. One way to satisfy this need is to control flowering (Meilan *et al.*, 2001). This may help alleviate or at least reduce public and regulatory concerns over the commercialization of transgenic trees. As discussed above, the manipulation of flowering can provide many benefits. Sterility can also reduce genetic pollution from nontransgenic plantations, promote vegetative growth, and eliminate nuisance tissues (e.g., pollen, seed pods). In addition, flowering control could lead to shorter juvenile periods.

While each strategy for engineering sterility has advantages, it is unclear which method will work best with trees. Hence, tests are underway that involve a variety of techniques, such as tissue-specific ablation, dominant negative mutations, and post-transcriptional gene silencing, including RNAi. Employing the first approach, Skinner *et al.* (2003) successfully used the promoter from *populus trichocarpa DEFICIENS* (*PTD*), a poplar homolog of the *Arabidopsis* gene *APETALA3*, to drive the expression of reporter and cytotoxin genes in floral tissues of *Arabidopsis*, tobacco, and poplar.

Recently, Wei *et al.* (2007) tested the utility of an attenuation system designed to avoid the harmful effects of leaky cytotoxin gene expression in the vegetative tissues of transgenic trees. They tested the promoter from the poplar *LEAFY* gene, *populus trichocarpa LEAFY* (*PTLF*), to drive *barnase* expression (*PTLF::barnase*). The same plants were also transformed with *barstar* driven by either the basal 35S promoter (+5

to -72 fragment, 35SBP); 35SBP fused to the tobacco mosaic virus omega element; or the *NOS* promoter. It was not possible to recover transgenic plants using unattenuated PTLF::*barnase*, leading the authors to speculate that this promoter led to substantial vegetative expression. While the *barstar*-attenuated constructs did permit the recovery of transformants, the rate was reduced. Seven percent of the attenuated events had highly abnormal morphology; these events had significantly higher *barnase:barstar* expression ratios, and were identified during the early phases of propagation. A greenhouse study showed that phenotypically normal attenuated plants grew at the same rate as WT and *barnase*-lacking transgenics. In addition, the authors demonstrated a positive correlation between relative growth rate and the *barstar:barnase* expression ratio in attenuated plants. Surprisingly, the appearance and growth rate of the nearly all of the attenuated lines were substantially reduced after one or two growing seasons in the field.

Recently this same group has been working with genes that affect flowering time. RNAi was used to reduce expression of the poplar ortholog of *CENTRORADIALIS* (*PtCENLI*), a gene that plays a key role in maintaining the tree in a juvenile condition. When transgenic poplars containing this RNAi vector were grown under field conditions, four of most strongly silenced lines produced inflorescences or floral buds within two years of planting, which was several years earlier than that seen in WT trees. Surprisingly, overexpression of *PtCENLI* also resulted in delayed vegetative budbreak (Mohamed, 2006). Based on this work, it appears that *PtCENLI* is involved in regulating release from winter dormancy and resumption of growth (Mohamed, 2006). Hopefully, this work will ultimately lead to the development of methods for shortening breeding cycles.

Despite indications that one or more of the strategies can be successfully used to engineer transgene confinement, no single method fulfills the basic requirements for long-term commercial use. Researchers are continuing to determine whether sterility can be complete and stable over several rounds of propagation and growing seasons, successfully identified in juvenile trees, and lack negative growth impacts.

2.6.4 Stature control

In many plants, DELLA-domain proteins, including *GA-INSENSITIVE* (*GAI*), *REPRESSOR OF GAI* (*RGA*), and *RGA*-like 1-3 (*RGL1-3*) have been shown to regulate GA responses. Through the use of transgenesis, Busov *et al.* (2006) demonstrated that DELLA-less versions of *GAI* and *RGL1* led to dramatic shoot dwarfing in *Populus*. This phenotype was associated with reductions in the levels of precursor GAs (e.g., GA_{53,44,19,20}) and dramatic increases in biologically active GAs, such as GA₁ and GA₄. In these same trees, root growth was enhanced twofold to threefold, and adventitious root formation was inhibited. Transgene expression also led to significant changes in the metabolic profiles of both roots and shoots. The observed metabolite changes may cause reduced carbon flux through the lignin biosynthetic pathway, and an increase in the allocation of secondary compounds to storage and defense molecules. These varied responses provide insight into the way in which poplars integrate ecophysiological adaptation. This family of genes could also enable the manipulation of shoot and root architecture and tree metabolism that could affect productivity, flowering, and drought and pest tolerance.

2.6.5 Importance of field tests

Transgenic plants need to be field tested for several reasons. The first is proof of concept—it must be shown that the inserted gene is having the expected effect. *A. tumefaciens* is widely used to insert genes into plant cells, but these insertions occur at random locations within the genome. The DNA surrounding the site of insertion influences the efficiency with which the transgene is expressed (i.e., “positional effects”). In addition, transgenes can be differentially expressed under various conditions (Walter *et al.*, 1992; Neumann *et al.*, 1997; Köhne *et al.*, 1998; Scorza *et al.*, 2001). Thus, it is important to screen all independent lines to verify that the transgene is being expressed at commercially useful levels. It may also be necessary to conduct field trials to determine if there is sufficient value so that end-users are willing to pay a biotechnology premium (i.e., licensing fee) for use of a GM tree. Finally, long-term field

studies are needed to detect somaclonal variations and assess the stability of transgene expression (Meilan *et al.*, 2002a, 2004a), and the ecological implications of deploying transgenic trees across the landscape (Farnum *et al.*, 2007.). The latter will be essential for gaining public and regulator acceptance of tree biotechnology.

3. FUTURE ROAD MAP

In 2006, the poplar research community achieved a very important milestone for the entire field of biotechnology. In this year, the sequencing of the first tree genome was published, adding it to the short list of higher plant genomes that have been fully sequenced, namely, *Arabidopsis* and rice (Tuskan *et al.*, 2006). The genome of a *P. trichocarpa* tree was completely sequenced six times over and this sequence has now been released for public use. Many previously unavailable avenues will now be open for tree researchers. Since we now know that ~45 000 genes are present in the poplar genome, aggressive, genome-wide functional genomics experiments will hinge on the availability of successful transformation protocols. Availability of a whole genome microarray chip, such as those produced for other species by genomics companies like Affymetrix and NimbleGen, will allow researchers to explore the transcriptional road map. This will allow a better understanding of various biological processes in trees (e.g., Mellerowicz *et al.*, 2001) that so far have not been amenable to such experimentation. The poplar research community will also benefit from the availability of these new tools that allow us to pose and resolve previously unanswerable questions. Integration of active proteomics, metabolomics, and phenomics projects will be necessary to interconnect available information and gain a system-level understanding of how trees develop, grow, and respond to the environment (Tsai *et al.*, 2006). Poplars will become a leader in such experiments. Recently, poplars have provided excellent “proof-of-concept” system for employing transgenics toward improving economically important and environmentally beneficial traits in other tree species. These discoveries have laid the foundation for field testing of transgenic trees by universities and forest-products industries

(e.g., Frankenhuyzen and Beardmore, 2004; Nehra *et al.*, 2005). We can predict only a bright future for all poplar research in the years to come.

For achieving such a far-reaching impact, we need to address some road blocks that may stymie future developments. Not all poplar species and genotypes are yet amenable to efficient transformation and regeneration procedures. Special attention should be given to those genotypes that are of commercial importance. It is well known that most of the economically important genetic traits are controlled by multiple genes and so single-gene transformation may not be sufficient. Better protocols for multiple gene transfer must be established and applied. Some success in this has been reported in poplars (e.g., Li *et al.*, 2003) by using co-cultivation methods, but these techniques are ineffective for genes with transcripts greater than 3 kb. Rather than using constitutive expression of genes under the 35S promoter, availability of inducible promoters that regulate expression of genes in a tissue-specific and temporal-manner will be essential for the successful transfer of lab results to field trials (e.g., Filichkin *et al.*, 2006a). Due to a genome duplication event, multiple copies of the same gene may exist in the poplar genome (Tuskan *et al.*, 2006). For example, we have observed that multiple copies of secondary wall-associated cellulose synthase genes are transcriptionally active during wood development. One copy of the gene, however, expressed at a much higher level than the other in most cases. This situation will complicate the functional genomics assays and the application of techniques such as RNAi, which have the potential to silence all copies of a given gene from the poplar genome. Generally, a combination of multiple transcription factors regulates expression of various genes in eukaryotes. Functional dissection of the role of each transcription factor from the poplar genome in biologically and economically important processes is an enormously important undertaking. Genomics advancements such as ChIP-on-Chip will greatly help to further such objectives (Thibaud-Nissen *et al.*, 2006).

A systematically conducted field trial is always necessary for examining the cause–effect relationship between the introduced gene and the phenotypic changes associated with *Agrobacterium*-mediated transformation. However, in countries such as Japan, regulatory authorities require

an extensive risk assessment evaluation before permission for a field trial is given. There is also increasing public concern about the presence of the antibiotic resistance genes commonly used as selectable markers during transformation. Since trees are long-lived species, this aspect is much more important for them than for the crop plants. Moreover, people view trees as a more natural and pristine resource than the feedstocks and crops used to sustain human populations. Lastly, in order to stack more than one gene in any single transgenic tree, we will need to use a variety of selection markers, possibly combining herbicide and antibiotic resistance traits. Ebinuma *et al.* (1997) developed a highly efficient vector system called MAT (multi-auto-transformation) that assists in removal of marker genes and increases the regeneration frequency of transgenic plants without using antibiotic selection. The MAT vector system uses natural oncogenes of *Agrobacterium* such as *ipt* (isopentyl transferase) and *indoleacetamide hydrolase and tryptophan monooxygenase (iaaM/H)*, thus making them hormone independent. This system also possesses the site-specific recombination system, including a recombinase (R) and defined recognition sites (RS). The oncogenes assist in regenerating transgenic plants on hormone-free media but are later removed by the induction of the R/RS system, thus producing marker-free transgenic plants. By manipulating the promoters that regulate the expression of the oncogenes and the R gene, transgenics have been produced for several economically important plant species (Ebinuma *et al.*, 2001), such as hybrid aspen. Examining the stability of introduced genes in transgenic trees is another important issue for tree biotechnologists (Kumar and Fladung, 2004). Insertion of multiple copies of the same gene at the same site in a transgenic plant has been observed to lead to transgenes silencing. Efficient methods for targeted insertion of transgenes at an appropriate position in the genome, therefore, must be developed.

Recently, Professor Steve Strauss co-authored several research articles and reviews concerning the potential utility of forest biotechnology and the need for additional field trials (e.g., Strauss, 2004a, b; Strauss *et al.*, 2004). About 800 poplar trees, including some transgenic trees, were destroyed

or vandalized in their experimental plots in 2001 (Kaiser, 2001). Such attacks jeopardize the basic tenets of science and prevent properly addressing, in a rational manner, the safety and usefulness of GMOs. Vandalism not only demoralizes researchers and deters them from performing important experiments, but is also counter-productive to our shared goal of logically and openly assessing the potential risks of genetically engineered trees.

In the US, the DOE has chosen poplars as a superior short-rotation woody tree in the production of bioethanol (Dinus *et al.*, 2001; Ragauskas *et al.*, 2006). A majority of the carbon in terrestrial ecosystems is sequestered in trees and, given efficient methods can be developed for conversion, can be used for the production of ethanol. Again, genetic improvement of cellulose and lignin production in trees, can, thus have a tremendous impact by producing cellulose with completely altered structural properties. The degree of polymerization, crystallinity, and quantities of cellulose will affect the usefulness efficiency of this process (Joshi *et al.*, 2004). This will require the identification of the poplar genes involved in hemicellulose production, which is a major component of dry wood. Previously identified transcription factors by Mendel Biotechnology that, when modified, produce larger plants in *Arabidopsis* provides optimism for identification of such genes in poplar. The list of such novel targets is always ever-increasing: (<http://www.mendelbio.com/products/yield.html>).

In conclusion, an intelligent combination of modern molecular biological tools and improvement of transformation efficiency in poplars will open many new avenues in tree biotechnology and substantially improve ecologically sound forest tree production.

ACKNOWLEDGMENTS

We wish to thank Prof. Chittaranjan Kole and Prof. Timothy C. Hall for inviting us to write this review on transgenic poplars. This topic has been actively reviewed in the past by others and readers are encouraged to refer to those papers for topics not covered here. We also want to thank Mrs. Rama Joshi for her help with the critical reading of the manuscript. Partial financial support for

preparing this review was provided by NSF (IBN-0236492), USDA (2005-35103-15256), and CPBR (G012026-249) funding to CPI.

1. INTRODUCTION

In the last century, the genus *Eucalypts* became an important multipurpose source of timber in many industrial applications for production of pulp and paper, charcoal, energy, furniture, and housing. The genus *Eucalyptus* is a member of the Myrtaceae family, mainly originated from Australia, comprising of more than 700 species (Brooker, 2000). The trees form tall open forests, woodlands, and occur in environments ranging from areas of high rainfall to semi-arid regions, and from sea level to subalpine altitudes. A few species have been described as occurring outside the Australian territory (Eldridge *et al.*, 1994); *Eucalyptus deglupta* is endemic to the Indonesian islands of Sulawesi and Ceram, Mindanao in the southern Philippines, northern New Guinea, and New Britain; *Eucalyptus urophylla*, *E. orophila*,

and *E. wetarensis* occur in Timor and adjoining islands of the Lesser Sunda group (Pryor *et al.*, 1995). Several factors contributed to the success of *Eucalypts*; the fast growth rate and large biomass production, the ability to grow in a wide range of environments and soils, good wood quality for solid wood products and short cellulose fiber, suitable for pulp production, particularly for paper and tissue. A considerable number of *Eucalyptus* plantations were established in the early 1900s in Brazil and South Africa along the railway tracks providing charcoal for the locomotives. Today, several countries in Asia, South America, southern Europe, and Africa, have an estimated area of planted forest around 16–19 million hectares (FAO, 2000). The predominance species in commercial plantations (around 80%) are *Eucalyptus grandis*, *E. globulus*, *E. camaldulensis*, and their hybrids (Potts, 2004). *E. grandis*,

E. urophylla, and their hybrids are mainly planted in tropical and subtropical regions, while *E. globulus* is preferred in temperate climates (Potts, 2004).

One important factor determining the expansion of large areas of commercial *Eucalyptus* plantations was the development of cloning techniques, initiated in 1975 in the Popular Republic of Congo (Delwaulle *et al.*, 1983). Outstanding genotypes, usually hybrids, having large and straight trunk with good wood properties were selected to make rooted cuttings and planted in large extensions of land. Vegetative propagation has been intensively used by the pulp and paper industry, producing highly uniform timber and allowing further gains in productivity in the pulping process. In the mid 1970s the development of tissue culture techniques and *in vitro* propagation of *Eucalyptus* spp. provided new opportunities for mass propagation, on a commercial scale, of selected genotypes. At the same time, the growing importance of *Eucalyptus* for the pulp and paper industry, particularly in South America and Africa, led to the establishment of breeding programs selecting better hybrids for cloning and to improve the basic populations introduced from Australia.

In the last 10 years, the advances in tissue culture techniques, plant regeneration, and genetic transformation, using mainly the *Agrobacterium* system, allowed the development of the first transgenic *Eucalyptus* trees. Also, advances in the use of molecular markers have played an important role in helping breeders to select *Eucalyptus* trees with better wood quality, disease resistance, and stress tolerance. More recently, the development of genomic approaches, such as major expressed sequence tag (EST) sequencing programs, have increased the interest in the application of biotechnological tools in order to produce better *Eucalyptus* trees.

Our chapter provides an overview of the main topics involved in *Eucalyptus* biotechnology, from cloning and hybrids production, breeding, application of molecular markers, tissue culture and plant regeneration, genetic transformation, main diseases affecting the *Eucalyptus* plantations, wood quality for the pulp and paper industry, energy production and biomaterials, and also the identification of genes involved in disease resistance and wood formation through functional genomics.

1.1 Hybridization, Cloning, and Breeding

1.1.1 Hybridization and cloning of *Eucalyptus* spp.: evolution and its importance for the forest sector in Brazil

The development of forestry plantations for industrial purposes must be oriented to increasing industrial competitiveness in the distinct market segments. In such a scenario, forestry-based companies must take into account the influence that forestry raw material can have on their competitive capacity. The modern concept of competitiveness includes generating products to meet the customer's requirements at low costs, in a sustainable manner and with minimum environmental impact. Therefore, the development of tree breeding programs to obtain quick gains, and a well-established cloning system have become important. Vegetative propagation methods should rapidly transform the genetic gains, obtained through breeding, into benefits for the industry. One of the most efficient tools to acquire these objectives is the combination of interspecific hybridization and establishment of clonal forestry derived from superior hybrid individuals (Assis, 2000).

In this context, hybridization can have a great impact on tree breeding programs, combining superior wood characteristics with tolerance to biotic and abiotic stresses, thus representing a significant source of superior individuals, capable of introducing genetic gains into forest productivity and wood properties. Crossing species with different characteristics allows the production of complementary wood properties in trees to meet special industrial requirements.

The effective and quick integration of genetic gains obtained with hybrids into the industrial process depends basically on the existence of functional large-scale cloning systems. Mass vegetative propagation perfectly complements hybridization for producing clonal forestry and has some advantages over the sexual methods of mass reproduction of selected families, besides being the best way to commercially exploit the heterosis found in several *Eucalyptus* hybrid crosses. By capturing the total genetic variance (Zobel, 1992), vegetative propagation allows for maximum benefits from wood properties and

productivity, besides allowing for the production of more uniform raw material, which from an industrial point of view is highly beneficial to the industrial process and product quality. Therefore, tree breeding programs that focus on these aspects of the forest industry will have a great impact on the three important components of the competitive process: productivity, product quality, and production costs (Assis, 2001).

Recognizing the importance of hybridization and cloning in the context of industrial production has led to a rapid evolution of the techniques and processes that constitute these activities. As a result, methods to produce hybrid seeds and commercial cloning are now well understood and highly effective from the technical and operational perspective in *Eucalyptus* species. Developing the concept of indoor breeding orchards and the creation of artificially induced protogyny (AIP) has made controlled crosses operationally feasible. Hybrid production by controlled pollination is thus a simple and functional process. Indoor breeding orchards do not require flower isolation, saving a lot of time. On the other hand, AIP enables pollination without the need to emasculate the flowers. These two technologies allow large-scale controlled crossing, which is technically difficult to carry out and also economically unfeasible using traditional methods.

In the cloning systems for commercial-scale propagation, the development of microcutting and mini-cutting to replace rooting stem cuttings led to the development of super-intensive systems to produce vegetative propagules, which can now be done in much more controlled environments, allowing greater physiological and phytosanitary control. The use of more appropriate propagation facilities, with better environmental control, has contributed to improve rooting rates. The development of these technologies for *Eucalyptus* marked the beginning of a new cycle in the commercial cloning of vegetatively propagated plants, especially for woody species (Assis, 2001).

In the last two decades, cloning *Eucalyptus* spp. has produced relevant progress for the forestry companies, especially solving problems associated with diseases such as canker (*Cryphonectria cubensis*) and productivity improvement (Campinhos and Ikemori, 1983). Currently, the focus on cloning has shifted to industrial requirements, rather than remaining limited to disease resistance and

increased volume. Wood properties that positively influence industrial processes and product quality are considered, especially where cloning has an important role to play.

1.1.1.1 *Historical and technical evolution of Eucalyptus hybridization and cloning in Brazil*

Hybridization Considering the length of forest production cycles, the commercial use of *Eucalyptus* hybrids is relatively recent in Brazil. Spontaneous hybrids randomly formed at the tree farm in Rio Claro, São Paulo, at the Companhia Paulista de Estradas de Ferro, provided the base for the first plantations for industrial purposes. These hybrids highlighted aspects of resistance to Eucalypt canker (Ferreira, 1997; Alfenas *et al.*, 2004) and to the presence of heterosis at the individual level during the 1970s. Therefore, these hybrids were also the starting point for the introduction of the concept of clonal forestry in Brazil, during the same decade (Campinhos and Ikemori, 1980). In the 1980s, when the importance of hybrids for industry was recognized, hybridization became an essential tool, helping to create a strong and competitive forestry industry (Assis and Mafia, 2007).

The first synthetic *Eucalyptus* hybrids were produced in the 1970s by open-pollination between compatible species (Assis, 1985; Gomes, 1987; Martins and Ikemori, 1987). Since this technique was limited by crosses between species that flowered at the same time, in the 1980s a controlled crossing method was developed in South Africa (Hodgson, 1967; Van Wick, 1977). Although it was difficult to perform, it enabled the expansion of hybrids produced artificially in Brazil (Brigatti *et al.*, 1983; Assis, 1985; Martins and Ikemori, 1987). This method is based on the exploitation of protandry where pollen reaches physiological maturity in anthesis, but the stigma is not receptive for another few days. To make controlled crosses using this technique, the flowers must be emasculated, isolated, and pollinated after 5–7 days. Therefore, the method has a low operational yield, mainly because of the number of visits needed to make the crosses (Harbard *et al.*, 2000). Moreover, relatively high losses are caused by injury to the flower buds during emasculation and

isolation, contributing to reduce the efficiency of the crossings.

In 1996, a new technique for controlled crossing was developed, called AIP. This new technique was initially developed at Riocell S.A. (Assis and Jardim, unpublished results) and its great advantage is higher operational yield and better use of the flower buds. This technique was conceived based on two discoveries made in Chile and in Portugal. OSP (one stop pollination) was developed in Chile (Harbard *et al.*, 2000), allowing receptiveness induced by cutting lengthwise or cutting off the upper third of the pistil of emasculated flowers. In Portugal, it was found that this receptiveness could be achieved before anthesis (Trindade *et al.*, 2001). AIP was developed by combining these two discoveries. This technique consists of the artificial transformation of protandry into protogyny, by cutting the top of the floral bud operculum. At the same time, the upper third of the pistil is cut during the preanthesis stage, i.e., when the flower is still closed, and pollen is applied immediately after induction. Thus, there is no need to emasculate the flowers to make crosses.

Later, this new technique was tested simultaneously in Brazil, at Aracruz Guaíba, and at Commonwealth Scientific and Industrial Research Organisation (CSIRO) in Australia (Assis *et al.*, 2005) with the same success rate observed at both sites. Besides reducing the number of visits, AIP does away with the need for emasculation and made it possible to obtain more seeds in *Eucalyptus*-controlled crosses. Operational productivity rose from 35 to 400 flowers per man/hour using this technique.

At the same time as AIP was created, the concept of indoor breeding orchard was developed, in screened houses, doing away with the need to isolate individual flowers, umbels or branches, enabling the isolation of whole plants in a collective way (Assis *et al.*, 2005). When some type of contamination is acceptable, this technique can be implemented in open areas that are not isolated. Currently it is the most widely used method for *Eucalyptus*-controlled crosses. The development of indoor breeding orchards was enabled by the development of technologies to induce early flowering in potted plants. Flower production in small plants is necessary to cultivate them within greenhouses and also to allow easier access to the

floral buds. In order to obtain flowered plants in pots, grafting of physiologically adult branches is used combined with application of the flowering inductor paclobutrazol.

The combined use of these technologies (AIP and indoor breeding orchards) allows large-scale controlled crosses and enables the multiplication of highly superior full-sib families, a task formerly considered technically and economically impossible. This is very important to improve difficult-to-root species, since the superiority of pure or hybrid full-sib families can be captured and multiplied on a large scale. This technique is widely disseminated in forestry companies and now accounts for most controlled crosses performed (Assis and Mafia, 2007).

Cloning techniques The first rooted eucalyptus cutting was obtained in Australia in the 1940s (Eldridge *et al.*, 1993). During the next decade, studies carried out by French researchers in the Congo, Tunisia, and Morocco played an important role in understanding physiological phenomena involved in the rooting of *Eucalyptus*, such as juvenility and maturation, as well as aspects of rejuvenation in *Eucalyptus* and their importance in cloning adult trees. This knowledge was important to establish the concept of *Eucalyptus* clonal forests, which occurred in the 1970s in Tunisia (Chaperon, 1987) and in Aracruz in Brazil (Campinhos and Ikemori, 1980). However, the first large-scale cloning system was established in Brazil, by Aracruz, and it served as a model for the development of clonal forests, whose use was extended to other Brazilian companies and to several parts of the world. After the success achieved by Aracruz, it was quickly disseminated, and now it is the main system for the reproduction of *Eucalyptus* species and clones.

Until the 1990s, the development of cloning techniques for *Eucalyptus* species evolved relatively slowly. For over a decade, the commercial production of vegetative propagules continued to be done by the original system, in clonal banks, before being replaced by the clonal hedges system. On the other hand, the techniques initially used for the stem cutting rooting of *Eucalyptus*, as well as the rooting facilities, remained practically the same until the early 1990s. In 1992, the first great change in the rooting technique occurred when microcutting (Assis *et al.*, 1992; Xavier and

Comério, 1996) and later mini-cutting were created (Assis, 1996; Higashi *et al.*, 2000).

Microcutting is a rooting method where the propagules are obtained from shoot apices originating from micropropagated plants and in mini-cutting originating from auxiliary sprouts of plants cloned by stem cuttings. After rooting of the first shoot, the two techniques are identical, varying only in the origin of the initial propagule source. In some clones using mini-cutting, some propagation cycles (serial propagation) are required to reactivate before acquiring full rooting capacity potential. In microcuttings such propagation cycles come naturally by monthly *in vitro* subculturing of explants. Micropropagation is unnecessary for easy-to-root species because high levels of juvenility can be obtained easily by inducing basal shoots, therefore in such cases, mini-cutting is technically and economically feasible.

When plants are established in the mini-clonal hedges to form the mini-stumps by whatever means, multiplication is performed using the mini-cutting technique (Assis and Mafia, 2007). Microcutting and mini-cutting are the most modern concepts for cloning *Eucalyptus* species in large scale and they are currently the most widely used techniques in Brazil. The creation of these technologies was the watershed in the evolution of *Eucalyptus* cloning systems and they resulted in profound changes in the main technical segments that constitute this activity. It marked the beginning of a new cycle in the propagation of woody species.

A major consequence of creating microcutting and mini-cutting was the great change in the methods to produce vegetative propagules in large scale. The clonal hedges that had replaced the original clonal banks system at the beginning of the 1980s were replaced by the mini-clonal hedges. Propagule production began to be performed in a super-intensive manner, supported by hydroponic systems in controlled environments (indoor mini-clonal hedges). Currently, two hydroponic systems are used: sand bed with drip irrigation (Higashi *et al.*, 2000) and intermittent flooding (Campinhos *et al.*, 2000).

The development of these technologies also influenced changes in the conception of rooting facilities that were important for their evolution and improvement. When *Eucalyptus* cloning

attained industrial proportions, most of the physical structures used to root stem cuttings were extremely simple, consisting of partial shading and a misting system. When the mini-cutting technology began to be used, greenhouses had to be used to achieve greater control over the rooting environment. Their importance in rooting became clear and led to their widespread use. Therefore, at the same time as rooting methods were developed, a major evolution occurred in the propagation structures. On the other hand, the development of super-intensive vegetative propagule production systems in hydroponic mini-clonal hedges, with better nutritional and phytosanitary control of the mother plants, is technically and economically advantageous in the commercial production of *Eucalyptus* plantlets. Currently, mini-cutting is the cloning technique most widely used by the large Brazilian forestry companies.

In easy-to-root hybrid clones, micropropagation is not commonly used as a rejuvenation method or simply as a method to rapidly broaden the clonal base of recently selected clones. Except in the systems that use microcutting, where it is a mandatory phase, mini-cutting from sprouts of rooted stem cuttings has worked well for these species and the tendency is that micropropagation will no longer be used for this purpose, especially due to its high costs. Nevertheless, there are technical advantages in using micropropagated plants to form mini-clonal hedges, even in easy-to-root clones. In clones that are difficult to root, micropropagation is still a technique that can potentially increase predisposition to rooting. This class includes *E. globulus* hybrid clones that are increasingly used in plantations for pulp production.

1.1.1.2 Importance of hybridization and cloning in Brazil

In recent years, the growing integration between the different segments of industrial production based on planting forests has been a major factor in the development of technologies dealing with forest production for industrial purposes. The greater proximity between forestry, industry, and commerce has enabled an integrated view of the segments: forest × industrial process × product quality, which is the base for acquiring

competitive differentials in industries. In this way, new prospects arose in the development of technologies that could promote a positive impact on the industrial production chain and, consequently, on industry performance. On the other hand, the perception of the great economic gains by industry as a result of the increased quality of raw materials has significantly enhanced the genetic improvement programs, above all due to their capacity to promote quantitative and qualitative changes in the raw material.

In this context, increasing forest productivity and improvement of wood properties for industrial use are important demands on Eucalyptus breeding programs in Brazil. The main objectives of these demands are the reduction of operational costs, improving raw material performance in industrial processing, and rendering it appropriate for the manufacture of high quality products for different market segments (Assis, 2000). The main contribution of genetic improvement for the forestry-based industry is the generation of superior individuals that can lead to gains in forest productivity, industrial process, and product quality. The greatest challenges for tree breeders have been to use effective strategies to obtain individuals that are superior in both growth and wood quality. The main obstacles to overcome these challenges are that the species traditionally planted in Brazil present certain limitations concerning the wood quality, compared with other *Eucalyptus* species. In this context, interspecific hybridization is a very useful tool, especially since it allows transfer of genes from species with high wood quality but slow growth, to species that have an inferior wood quality but are well adapted to the planting sites and with excellent growth. The main advantage of hybridization, besides the capacity to allow the combination of differentiated characteristics in distinct species, is the possibility of producing trees with superior growth as a result of heterosis or hybrid vigor, a common phenomenon in Eucalyptus (Martin, 1989; Denison and Kietzka, 1992; Nikles, 1992).

The differences between the various species of Eucalyptus adapted to this country, with respect to wood properties, tolerance to biotic and abiotic stresses, as well as to the manifestation of heterosis has been the main factor to produce individuals with superior growth, adaptation, and wood quality, through hybridization. Thus, the

shortest path between industrial demands and their fulfillment by genetic improvement programs is to seek complementarity among species, by increasing the number of desirable characteristics of the wood, combined with the commercial utilization of heterosis. Enhancement of the forest quality by the commercial use of heterosis, through the vegetative propagation of Eucalyptus hybrids in Brazil is clear and there is evidence that it is a very useful phenomenon for a faster gain in forest productivity. In this sense, the contribution of Eucalyptus hybridization to forest development in Brazil is very significant. Most benefits from hybrid use, especially in forest productivity, are accredited to the manifestation of heterosis for growth and to the complementarity of certain species concerning characteristics that combine to produce more appropriate genotypes for the different planting environments (Assis, 2000).

Currently, the vast majority of Eucalyptus improvement programs in Brazil are based on hybrids. In 2005, 84.5% of the clonal plantings of Eucalyptus in Brazil were hybrids, where 66.5% of which were hybrids from controlled crosses. The hybrid *E. grandis* × *E. urophylla* is most often used, with 65% of the planted area. Fifteen percent of the remainder is still natural and spontaneous *E. urophylla* hybrids, 3% Rio Claro hybrids, 0.5% *E. urophylla* × *E. camaldulensis*, 0.4% *E. urophylla* × *E. globulus* and 0.6% *E. camaldulensis* × *E. grandis* (Assis, 2004).

Wood properties are very important for industry because they have an impact on processing costs, production gains, and the technological qualification of the products and are therefore essential in production processes of raw material for industrial use. In this sense, hybridization tends to play an increasingly important role in the Eucalyptus planting programs in Brazil. Because of the success achieved in southern Brazil concerning the incorporation of *E. globulus* genes into site-adapted species and clones, mainly due to the significant enhancement of the wood quality to make pulp, there is a tendency to seek the source of wood quality in this crossing, by pulp companies. A major breakthrough is expected in wood quality to make short-fiber pulp using *E. globulus* hybrids.

From the perspective of industrial processes, *E. globulus* is the most appreciated *Eucalyptus* species by the pulp mills, because its wood presents technological properties that are especially important

for the pulping process. Either because it provides greater production gains, or due to the lower manufacturing costs, its wood tends to be a major competitive differential point for the companies. Evaluations performed on *E. globulus* hybrids show that it is possible to maintain the same forest productivity levels obtained in *E. grandis*, *E. saligna*, *E. dunnii*, *E. urophylla* and several of their hybrids, but with positive changes in wood and pulp quality. Compared to the traditional genetic materials, these hybrids allow increasing wood density; reduction of 4% in lignin content; a 3% increase in pulp yield; 3% increase in hemicellulose content; 1 m³ reduction of wood per ton of pulp in specific consumption and a 5 kg reduction of the chlorine dioxide per ton of cellulose in bleaching, among others.

The forests that are being planted using the new genetic materials from this new type of crossing will provide major gains for the industries, significantly improving their competitive capacity on the short-fiber pulp market. Together with the gains in production and cost reduction, the variability found in the selected individuals also allows the obtention of fibers with anatomical characteristics that are appropriate for different market segments, allowing the qualification of pulp for each specific product.

The efficiency of hybridization to produce genetic gains is fully acknowledged, being used by most forestry companies in Brazil. However, since the hybrid offspring are heterogeneous, transforming these gains quickly and effectively into benefits for the industry depends on functional, large-scale cloning methods. Thus, if on the one hand, interspecific hybridization in Eucalyptus has been the fastest way to achieve genetic gains, cloning on the other hand is the most efficient way of incorporate these gains into the industrial production processes. Cloning as a tool for the implementation of clonal forests derived from high-quality hybrids, is still the ideal technical complement to maximize the benefits of hybridization in the context of forest production for industrial purposes. Currently its maximum potential has been achieved in establishing clonal forests derived from controlled interspecific hybrids, which produce better quality wood, greater volume, growth, and higher resistance to biotic and abiotic factors. In this way, cloning plays a major role and for this reason it has received much

attention in forestry research programs in Brazil. The consolidation of cloning as a method for the commercial reproduction of superior Eucalyptus trees had a positive effect on productivity, costs of industrial processes, and product quality. Cloning Eucalyptus in large scale is currently one of the most important factors in promoting increased productivity, improvement, and homogenization of wood technological properties as an industrial raw material (Assis *et al.*, 2004).

Almost 30 years after the introduction of the concept of clonal forests in Brazil, cloning is definitely a part of the raw material production processes used in various sectors of industrial activity, above all pulp and paper and charcoal, which account for 78% and 21% of the area planted with clones, respectively. In 2004, the area planted with clones surpassed 1 000 000 ha. The current annual rate of new clonal planting is over 250 000 ha, with a tendency for further growth.

Brazilian clonal forestry was initially developed from spontaneous hybrids and natural hybrids presenting heterosis for growth, besides resistance to diseases, above all Eucalyptus canker. Although these hybrids were produced empirically, they were responsible for the great breakthrough in forest productivity that occurred in recent years. Forest productivity was increased threefold by cloning them. Currently the clonal forests are derived from individuals generated in genetic improvement programs, whose main strategy is based on the production of controlled interspecific hybrids. The cellulose increment (AMI cell) was around 6 t ha⁻¹ year⁻¹ in the 1970s. This productivity is now around 12 t ha⁻¹ year⁻¹ for the leading companies in this industry. Using *E. globulus* in the composition of hybrids, it is expected that trees planted from 2010 onward will achieve productivities of 16 t ha⁻¹ year⁻¹.

1.1.1.3 Future perspectives

Due to the current importance of hybridization and cloning for industrial forests, their use has been consolidated and they are increasingly becoming part of the forest-based industrial production processes. The progress achieved in the different techniques involving these activities will ensure new levels of quality and constitute new platforms for the development of Brazilian forestry.

The advances that have occurred in controlled pollination techniques, for instance, will allow the intense use of hybrids in breeding programs of the industries that use *Eucalyptus* as raw material. On the other hand, hybrid production will be increasingly oriented to crosses with *E. globulus* and its subspecies, mainly because of the quality of this wood for pulp production. The use of adapted species and clones, combined with this species, has allowed a significant improvement in the wood quality, in environments where the pure species is not well adapted. This will allow the use of *E. globulus* hybrids both in subtropical and tropical areas, with significant gains in wood quality.

Although there has been significant progress in techniques and *Eucalyptus* rooting methods culminating in a robust, functional, well-established system, several studies on cloning are being performed to develop new systems that could be technically and economically more appropriate than the current ones. Propagule production methods evolved from an extensive system, with low propagule production per square meter, passing through an intensive system in clonal gardens until they reached the present super-intensive systems, with high propagule productivity per square meter in the mini-clonal hedges supported by hydroponics. The search for new advances in this field is directly related to establishing production systems for mini-propagules in bioreactors, using minimum space and with a significantly higher propagule production per square meter. A further advantage of these technologies is that they use highly rejuvenated tissues, which may provide better technical results both for plant production and for the quality of the clonal forests.

1.2 Factors Affecting Expected Genetic Gains in Forest Breeding Programs Using Seeds

Genetic improvement has the main objective of obtaining genotypes, through selection, that present adaptations to environmental conditions, resistance to disease and insects, characteristics desirable for productivity, and the multiple uses of wood. Many species of the genera *Eucalyptus* and *Pinus* have been intensely used in reforestation programs in Brazil and many other countries. The importance of *Eucalyptus* seeds of the

best quality, from the best origins and the establishment of test species, seeds and progeny allowed the selection of genetic material with the potential for adaptation and productivity under the edaphoclimatic conditions found in different regions of Brazil.

The beginning of any breeding program is the selection of the species and populations to be used, by species tests and the origin of the desired characteristics (Resende *et al.*, 2005). The strategies for genetic improvement of exotic forest species has been based on the selection of species/origins and the selection of individuals from the base population, exploring the natural genetic variability existing amongst populations and individuals (Ferreira, 1992). Vencovsky and Barriga (1992) concluded that the knowledge of the type of genetic action that predominates in the genetic basis of a character is an important ingredient in an efficient breeding program. Gene effects are classified into two basic types, allelic interactions (dominance interactions between alleles at an interlocus level) and nonallelic (epistatic actions that arise when alleles or genotypes are influenced by the genetic constitution of other loci).

According to Resende *et al.* (2005), based on experimental evaluation, the selection should be based on means and variance, recommending that the selected material should have an elevated mean and ample genetic variability, allowing continuous gains with selection through various generations. A way to estimate the progress of the selection process is very important when using quantitative genetics in plant improvement (Vencovsky and Barriga, 1992). By the general expression of gain (ΔG) " $\Delta G = ds \times h^2$ ", it can be observed that the progress is a direct function of the magnitude of the differential selection (ds = difference between the mean of the selected group and the mean of the original population) and of the heritability coefficient (h^2) (Wright, 1976; Zobel and Talbert, 1984). The expected progress varies in accordance with the selection scheme and is detailed by Shelbourne (1969), Vencovsky (1978), Vencovsky and Barriga (1992), and Cruz and Regazzi (2001).

Ferreira (1985) stated that the gains obtained depend on the standard used for comparison (selected material or not), the effect of age on the evaluation, and environmental variation at the

sites where the progeny were tested. Sometimes the expected genetic gain at a determined phase of the improvement program cannot be achieved. Factors related to the management of the improved populations, factors related to the production of seeds and saplings, genotype \times environment interaction and others, can contribute negatively and these factors are discussed individually below.

1.2.1 Selection of genetic material

The selection based on indices has been used in forest improvement, offering larger gains when compared to other selection methods (Cotterill, 1986). The utilization of selection indices in *Eucalyptus* spp. improvement requires the estimation of a series of parameters, indices, and progress with selection, to permit the breeder to choose an index adequate for each situation (Resende *et al.*, 1990). Resende *et al.* (2005) states that selection methods applicable to the perennial species can be classified in accordance with the selection units and the procedure used to predict the genetic values. According to the author, the procedure currently used to estimate the variation components and predict the genetic values is AM-BLUP (animal model, evaluation of genetic variation) associated with DFREML (derivative free maximum likelihood).

Oda *et al.* (1989) described the problems in classic genetic improvement with *Eucalyptus* due to high selection intensity, affirming that the risks of intense individual selection in genetic improvement can be reduced if the species used are pure and adapted, the matrices were selected under normal environmental condition (without stress), the size of the effective population is maintained high, and used for short-term programs. In asexual improvement, the authors suggest that better results could be obtained if hybrid species are used, the matrices were selected under stress, heterosis could eventually appear, and high intensity selection was used. The authors present results from experiments with *E. grandis* obtained under high selection intensities. A total of 51 selected trees, as well as the half-sibling progeny, were evaluated with respect to cloning. The selection of the trees was made using populations originally from Coff's Harbour (NSW, Austrália), under the intensity of 1:5000 and populations from

Zimbabwe, at 1:2000. Based on the evaluations of the materials from the different experiments, the following relationships between the characters were established:

- (a) Relationship between the flowering period, the typical qualities of the trees, and the behavior of the respective progenies (material from Coff's Harbour). It was observed that the same trees that originated from inferior progenies presented early flowering and atypical fruits, demonstrating the occurrence of hybrids in the selected material and a loss in productivity due to the heterogeneity in the trees.
- (b) Correlation of the clonal behavior with the behavior of the progenies using diameter at-breast-height (DBH) and height data and comparisons with the inheritance estimates of the progenies (material from Zimbabwe). A clone-progeny correlation for DBH ($r = 0.020$) was very weak (Figure 1) and low for height ($r = 0.33$) (Figure 2), this shows that clones with good performance do not always present good progenies. Gene dominance could favor the selection of heterozygotic trees and heterogenic descendents with low productivity.

This study shows that intense selection can reduce the effective size of the population, leading to the presence of different degrees of endogamy, demonstrating the loss of vigor in the saplings originating for endogamous crosses. In relation to the concept of the effective population size, Vencovsky (1987) discussed the genetic representativity contained within a sample in relation to immediately previous generation. Thus, the effective size is related to the genetic size of the population and not the number of individuals within the population (Resende and Vencovsky, 1990).

1.2.2 Correlations and correlated responses between characteristics

The study of the correlations between characteristics is important in genetic improvement, because the general preoccupation is to improve the material, not only for isolated characteristics but simultaneously for a group of characteristics (Vencovsky, 1978). According to the author,

Figure 1 Correlation between the DBH values (cm) for progenies (2 years) × clones (3.5 years) [Source: Oda *et al.*, 1989]

the expected alteration in the mean of a determined characteristic Y, when the selection is for characteristic X is a response correlated with the system of selection considered. The correlation visualized directly in an experiment is phenotypic in nature, provoked by two factors: genetic and environmental (Vencovsky and Barriga, 1992). In genetic improvement it is important to know the association between characteristics, especially when the selection of one of them presents

difficulties, such as low heritability or in the measurement or identification (Cruz and Regazzi, 2001). According to the authors, in genetic studies it is important to differentiate and quantify the degree of genetic and environmental association between the characteristics, such that the genetic correlations are of a heritable nature and as such usable in breeding programs.

Cruz and Regazzi (2001) discussing simultaneous selection of characteristics stated that the

Figure 2 Correlation between the height (m) for progenies (2 years) × clones (3.5 years) [Source: Oda *et al.*, 1989]

use of the index theory of selection is an efficient alternative, permitting the combination of multiple information contained within the experimental unit and making possible selection based on a number of variables that unite various attributes of economic importance. The authors reviewed various proposals to obtain selection indices (classic index proposed by Smith, 1936 and Hazel, 1943; index based on desired gains; base index; index based on the sum the ranks; “weight free” and “parameter free” index).

In *Pinus radiata*, Dean *et al.* (1983) studied 30 families of half-siblings and detected negative correlations between volume and wood basic density. The gain estimates for these characteristics, combined into one index, revealed that it is not possible to improve wood density and volume simultaneously. Moraes (1987) detected a low negative genetic correlation between growth characteristics and wood basic density in open-pollinated *E. grandis* progeny. However, this correlation was not sufficient to seriously weaken the possibility of gains in wood basic density.

Reviewing other genetic and phenotypic correlations between wood basic density and growth characteristics, Moraes (1987) observed the existence of high correlations between height, DBH, and volume, however a correlation between these characteristics and basic wood density was of different magnitudes, both positive and negative. For Sturion (1993) these contrasting results demonstrate that generalization could provoke losses in a selection process, depending on the adopted strategy.

1.2.3 Endogamy

According to Wright (1976), endogamy signifies the crossing of related individuals or descendents of the same individual. The most extreme case of endogamy is self-fertilization; however, there are various degrees of endogamy before this, such as crossing between siblings and members of small isolated populations. The author further states that endogamy does not always cause a reduction in vigor or depression by endogamy, which is caused by the accumulation of recessive deleterious genes and not solely because of self-fertilization.

Eldridge (1978), working with the proportion of self-fertilization and open-crossing in Eucalypts,

confirmed predominance for open-crosses, although this proportion differed between species. Reddy and Rockwood (1989) reported that the quantity of self-fertilization in Eucalypts is higher than 7%. Estimates for the degree of natural self-fertilization vary among the species of *Eucalyptus*: 24% in *E. obliqua* (Brown *et al.*, 1975), 18% in *E. stoatei* (Hopper and Moran, 1981) and 10–38% in *E. grandis* (Hodgson, 1976a).

Hodgson (1976b) studied some aspects of flowering and the reproductive system in *E. grandis* and observed that progenies from self-fertilization were subject to various forms of endogamic depression, including deformation of the leaves and stem, reduction in vigor in comparison with progenies from open-crosses. The author concluded that the product of a seed producing plantation suffers a degree of reduction because of the quantity of self-fertilization, estimated at 30% (Van Wyk, 1981).

Various studies were carried out in order to verify the effects of different degrees of endogamy in Eucalypts, such as Van Wyk (1981), Eldridge and Griffin (1983), Maêda (1987), Griffin and Cotterill (1988), and Hardner and Potts (1995). Eldridge (1976) stated that endogamic depression in Eucalyptus is expressed as low growth of the saplings in the field and low viability of their seeds. Eldridge and Griffin (1983) working with *Eucalyptus regnans*, observed that the number of seeds varied from 42 per 100 in self-fertilized to 71 seeds in open-pollinated and 90 seeds in cross-pollinated flowers.

Irregular flowering and a deficiency in pollination are factors that can provoke endogamy. The presence of endogamy causes various prejudicial effects in Eucalypts, including deformed leaves and stems, reduction in vigor of the saplings, reduced height, reduced survival of saplings in the field, and reduction in the production of viable seeds.

1.2.4 Progeny tests

Individuals selected using an estimation of genetic parameters are then analyzed using progeny tests to ascertain their reproductive value as seed producers and later used to form seed producing plantations (Kageyama, 1980). Shimizu *et al.* (1982) presented the procedures and

recommendations for the installation of progeny tests.

The best way to evaluate the genotypic value of the selected trees is through their progenies, permitting the estimation of their value as progenitors (Weir, 1977). This procedure permits the separation of trees with phenotypic superiority caused by the good planting conditions from those that present genotypic superiority (Allard, 1971; Weir, 1977). Hodge *et al.* (1996) compared the genetic parameters of progenies by open-pollination and controlled pollination, using *E. globulus* and *E. nitens*, and evaluated using two types of populations resulting from open-pollination (native population and a seed producing plantation) and two types of populations resulting from controlled pollination (using families of siblings from self-pollination and pollination between individuals). For *E. nitens* two populations were evaluated, families from the seed producing plantation using open-pollination and self-pollinated sibling families. The progeny tests were established at various sites and after 2 years height, DBH, and cylindrical volume were measured. The authors observed that early estimates of heritability for the open-pollinated progenies derived from native populations could be exaggerated, probably due to the high degree of endogamous depression. It was concluded that genetic gain estimates of open-pollinated populations can be overestimated because of (1) inflated heritability estimates and (2) flaws in the evaluation genotype \times environment interaction.

One point to be discussed during the installation of the progeny test is sapling preparation. Generally the selection of saplings is made in order to make the forest more productive and homogenous. The appearance of abnormal saplings could be linked to endogamous effects; however Nogueira (2005) observed that a controlled cross carried out using two unrelated *E. grandis* trees, resulted in progeny with a 3:1 proportion of normal and abnormal individuals, respectively. The study identified two random amplified polymorphic DNA (RAPD) markers linked to the principal gene that causes the abnormal phenotype.

The preparation of saplings for the installation of progeny tests for *E. grandis* was studied by Mello *et al.* (1993). The authors studied the influence of two systems for the utilization of seeds on the behavior of 14 progenies and three controls, using

two methods of sapling preparation: (a) seeded directly into tubes, thinned and selected and (b) seeded into a germinator, planted and utilize all the seedlings. At 2.7 years of age, the results indicated that significant differences exist between the two systems. The progenies presented superior DBH, basal area, and cylindrical volume when submitted to sapling selection in the nursery. It was also observed that there was a significant interaction between the progenies and the sapling production system.

1.2.5 Seed production

When the seed production plantation is established, it is expected that the seeds produced represent the desired crosses, and it is important that the pollination is effective between the genetic material present in the plantation. Mora *et al.* (1981) reviewed the aspects of seed production in forest species, citing various authors who emphasize that abundant flowering and the production of good quality seeds depend on various factors related to the processes of pollination, pollen germination, pollen tube growth, fertilization, and embryo development. Thus, the success of the plantation depends, among other things, on the quality of the pollen produced and germination efficiency. Contrasting differences in the germination efficiency of the pollen between the selected genetic materials in the plantation, would suggest that not all the materials will participate equally as the masculine progenitor. Thus, it is important to evaluate pollen viability in the trees selected as part of the breeding matrices and to detect male sterility. It is also important to study tree management techniques that influence pollen quality.

Weir and Zobel (1975) discussed seed production plantations for selected material. According to the authors, the strategy to develop and test material adequate for future generations should be elaborated early, during the first generation of the improvement program. If the program is of long duration, the consequences of a restricted genetic base and associated risk of endogamy should be avoided by the continuous inclusion of new genetic material within the population. Thus, the ideal way to select the maximum number of unrelated individuals for advanced generations is diallelic

or partial diallelic, both give good estimates of the parental value of the clones, and general and specific combining abilities of the parent trees.

Kellison (1969) stated that due to the fact that seed productivity is dependent on environmental variables, the geographic location, plantation area, and clone dispersal should be considered before a seed producing plantation is installed. For the installation of plantations for the production of hybrid seeds by open-pollination, the following points should be considered: (a) that the species have coincident flowering; (b) the ratio of pollen receptors to pollen donors should be adequate to favor hybridization; (c) the pollen receptor species should have a shorter period of flowering in relation to the pollen donor species; (d) the pollen receptor species should be relatively or completely self-incompatible; and (e) the selection of hybrid saplings in the nursery is essential and should be preceded by studies on the architecture and inheritance of the characteristics of interest to assess its operational viability. The hybrid seeds produced by controlled pollination and the progeny tests are the base of this study.

Basic studies such as the phenology of the selected clones, determination of the general and specific combining abilities and self-compatibility studies are necessary to conduct a prudent improvement program in order to achieve the pre-established objectives.

1.2.6 Pollen viability

Studies on Eucalyptus pollen, in general, aim at developing techniques adequate for pollen management, including genetic conservation, controlled production of hybrids, and the determination of pollen quality/viability. Sousa and Pinto Jr. (1993) reported the existence of intra- and interspecific differences in pollen germination; these could be genetic or physiological in origin, suggesting the need to develop specific culture media that imitate natural conditions. Studies on the *in vitro* germination of Eucalyptus pollen were carried out by Boden (1958), Gabrielli *et al.* (1965), Borges *et al.* (1973), Griffin *et al.* (1982), Cangiani (1988), Sousa (1988), Menck *et al.* (1990), and Sousa and Pinto Jr. (1993).

Sousa (1988) stated that the nutritional state of the plant during pollen development could

affect longevity. Due to the general opinion that boron is necessary and germination efficiency is poor in media with only sucrose, Sousa (1988) studied the effect of boron and calcium on *E. urophylla* and *E. tereticornis* pollen germination. The authors concluded that boron was necessary although they were unable to define the exact concentration. Therefore, the nutritional status of the seed producing trees, with particular respect to boron, is very important. On the other hand, calcium doses of 220 ppm improved the germination efficiency of the two species tested. It would be interesting to observe the effect of boron supplements in the seed production plantations with respect to pollen viability and seed quality.

Suzano Company evaluated 55 *E. grandis* matrices of a second-generation clonal seed production plantation, from different origins, that are part of Suzano's breeding program. Branches containing flowers were collected, the open flowers and the green buds were removed, and the branch was placed in a recipient with water and left in the greenhouse. The buds in anthesis and the open flowers were cut from the branches and the stamens were removed for pollen extraction. A large variation in the efficiency of pollen germination was observed between the trees analyzed, the amplitude of the variation was from 0.15 to 93.96%, with a mean of 44.77%. This variation in the efficiency of pollen germination was also observed by Boden (1958). As these trees are part of the Suzano's clonal seed orchard, second generation, this data is important to evaluate the pollination among the selected genetic material. Thus, variations in pollen germination efficiency will influence the pollination within the plantation and as such influence the genetic quality of the seed. To investigate pollen germination efficiency between locations, the variation in five different locations was determined: Location 1 = 2.56–92.45%, Location 2 = 10.78–69.92%, Location 3 = 25.03–79.17%, Location 4 = 0.15–82.74%, and Location 5 = 1.22–93.96%. From these data, it can be observed that there is an ample variation in germination efficiency within the progenies used, with the range of efficiencies varying with location probably due to physiological/environmental factors. Thus, any variation detected at the same location should be due to genetic effect.

According to Eldridge (1976) there are only a few examples of male sterility in Eucalypts. The detection of these individuals is important since these trees will not participate as pollen donors.

1.2.7 Pollination

In natural populations, Eucalypts exhibit a mixed crossing system, but predominantly allogamy (Griffin, 1989). The pollination of the genus *Eucalyptus* is mainly entomophilic with the principal pollinator being the bee, *Apis mellifera* L. (Pacheco, 1982). Novelli *et al.* (1982) investigated the influence of bee pollination on seed production in a clonal plantation of *Eucalyptus citriodora* and demonstrated an increase in the number of viable seeds per kilogram and the number of capsules per panicle. Pacheco (1982) studied the effect of bee hives (*A. mellifera* L.) in a seed producing plantation of *E. saligna* on production and quality of the seeds. The pollen from the trees in the center of the plantation were labeled using P³² and it was shown that the number of flowers containing labeled pollen decreased with the increase in distance from the source up to a distance of 300 m. Other results demonstrated a gradual reduction in the number of seeds per fruit with an increase in distance from the hive. At 0–50 m, the number of seeds was 40% higher than that from 300 to 350 m from the hive, with the authors demonstrating pollination activity of the bees up to a distance of 350 m from the hive.

Maêda (1987) estimated for an *E. grandis* seed producing plantation, the fertilization rate for the characteristic that produces albino plantlets. The observed rate was 5.57, which represented a coefficient of endogamy of 0.03. The author considered this rate to be low and the variability of the plantation was maintained by efficient insect pollination. Although there appeared to be a large number of insects present on the plants, only a few effectively participated in the movement of pollen between flowers. When the quantity of pollen transported, visiting frequency and movement among the flowers was observed, *A. mellifera* was confirmed as the most important insect in *E. grandis* pollination.

According to Griffin (1989), pollen is frequently transported to larger distances than those inferred by direct observation of the insect flight behavior. The pollen collected from one flower is not

necessarily deposited in the next to be visited. The biological aspects of the Eucalyptus flower suggests that (a) feeding behavior is not strongly conditioned by flower structure, therefore sticky pollen could be distributed over the whole insect, not solely the part that enters into contact with the stigmas and (b) pollen can maintain its viability for approximately 8 days on the insect's body, indicating that the transported pollen remains functional during this time.

Barbour *et al.* (2006) evaluated the phenology of flowering in species of the subgenus *Symphyomyrtus* native to Tasmania and *E. nitens*, introduced species. The difference in the flowering period of the native and an introduced species was highlighted as the principal barrier to gene flow by pollen. The authors state that the results show the importance of knowing the factors that affect gene flow, with the objective of identifying species and populations, native and exotic, with the highest risk of gene flow.

Griffin and Hand (1979) stated that knowledge about the receptiveness of the stigma, besides the processes of floral development and pollen release, is fundamental to the study of reproductive biology. Sousa and Pinto Jr. (1993) studied stigma receptiveness in *E. dunnii* in order to suggest ways to improve the efficiency of controlled pollination. The authors observed that for maximum efficiency, consequently better seed production, pollination should be carried out on the 6th day after anthesis. The receptive period for Eucalyptus stigma can vary within the subgenus (Pryor, 1951), between species of the same subgenus (Griffin and Hand, 1979) and within the same species. Griffin and Hand (1979) highlighted that there could be differences in floral receptiveness within the same tree. The similarity in floral development rates of different species within the same subgenus *Symphyomyrtus*, but growing in different hemispheres, suggests to the authors that this process is under strong genetic control.

According to Eldridge (1976), the flowers of Eucalyptus are hermaphrodite (male and female in the one flower), because protandry has been observed in some species, with examples of self-incompatibility and male sterility; however, allogamy can be considered as predominant in the genus. Although protandry occurs, this does not eliminate the possibility of self-fertilization, since flowering in the canopy lasts longer than the receptive period of a flower.

Kageyama (1979) studied the isolation of seed production areas, trying to minimize undesirable pollination problems because of the facility in intercrossing between large numbers of *Eucalyptus* species. The fact that pollination is predominantly entomophilic within the genus highlights the need to take care in the minimal distance between plantations to prevent possible contamination. A minimum distance of 200 m between seed production areas is recommended. The authors also suggested the use of barriers consisting of other genera or unimportant *Eucalyptus* species to effectively isolate the seed production areas.

1.2.8 Floral development, phenology of flowering, and fruit formation in *Eucalypts*

The period and intensity of flowering varies within and between species, especially where they grow as exotic plants (Griffin, 1989). This could cause two sorts of problems: firstly, when the populations selected for improvement contain material from different origins they could function as a series of subpopulations partially isolated because of the different flowering periods, decreasing the effective size of the population and increasing the risk of endogamy; secondly, variations in the interaction between the species and the insect vector could affect the pollination efficiency between members of the population.

Studies on floral development and flowering/fruiting intensities in *Eucalyptus* populations have been carried out by Moggi (1959) with *E. camaldulensis*, *E. resinifera*, *E. rudis*, *E. tereticornis*, *E. botryoides*, and *E. gomphocephala*; Hodgson (1976a, b) with *E. grandis*; Ashton (1975) with *E. regnans*; Ferreira (1977) with *E. grandis*; Mora and Ferreira (1978) with *E. urophylla*; Aguiar and Kageyama (1987) with *E. grandis*; Graça (1987) with *E. dunnii*; and Souza (1996) with *E. camaldulensis*. Mora and Ferreira (1978) studied the flowering of *E. urophylla* clones in Piracicaba (SP, Brazil). For each clone a branch was chosen to represent flowering in order to follow floral development in accordance with the following stages: (a) inflorescence formation, without individualization of the floral buds until the first operculum falls; (b) from the fall of the first operculum to the fall of the second; (c) flowering (opening of the floral bud); (d)

Table 1 Comparison of the number of viable seeds per kilogram in populations of *E. grandis* with different degrees of genetic improvement

Degree of genetic improvement	Number of viable seeds (kg ⁻¹)
SCA (seed collection area)—Austrália	400 000 to 800 000
SCA—Brasil	800 000 to 1 000 000
SSO (seed orchard by seeds)	80 000 to 400 000
CSO (clonal seed orchard)	500 000 to 1 000 000

fruit development; and (e) natural seed release. Proposing a vision more quantitative, percentages were calculated related to the production and development of the flower buds, flowers, and fruits. The authors observed that, in general, from the initial development of the buds to flowering takes 4–5 months and fruit formation to natural seed release 7–8 months. The natural loss of floral buds during flowering, fertilization, and fruit formation was 54.85%. The flowering period varied among the clones and could be put into the following categories: clones that did not flower during the experimental period; clones with an extremely short flowering period; clones that flowered almost the whole year; clones with a flowering peak from November to February; clones that flower from April to August; and clones with incompatible flowering characteristics.

Mori *et al.* (1988b) suggested that to obtain maximum production, it is necessary to know the factors that affect productivity and use management techniques to alleviate these problems. Thus, basic knowledge about the biological process involved in seed production is important to predict and study the factors that could reduce productivity (Mora *et al.*, 1981).

The variations in the number of viable seeds per kilogram could be related to the pollination efficiency, frequently weakened by the high variability in flowering or restricted genetic bases are shown in Table 1.

1.2.9 Seed vigor and size, germination and initial development of the seedlings

The level of physiological quality of the seeds should be evaluated through their capacity to

germinate and seedling vigor (Popinigis, 1977; Aguiar, 1984). Popinigis (1977) suggested an index for the speed of emergence (SEI) in the determination of relative vigor between lots of seeds and an index for the speed of germination (SGI).

Valeri *et al.* (1984) commented that previously published papers demonstrate that the size of the seed is one of the factors that affect germination, with larger seeds producing more vigorous plantlets that develop faster. Thus, a classification by size would reduce losses associated with the less vigorous plantlets produced by small seeds that are quickly dominated by the plantlets from larger seeds (Aguiar *et al.*, 1979). The authors studied the influence of *E. saligna* seed size on germination and initial plantlet development. The results demonstrated that plantlets from larger seeds reached the size for thinning and transplanting quicker than those from smaller seeds. Similar results were obtained by Pereira and Garrido (1975) with *E. grandis*, observing that larger seeds presented a higher SEI than the smaller seeds.

The occurrence of self-pollination contributes to the loss of seed quality, provoking the appearance of albino and abnormal plantlets (Kageyama, 1981; Maêda, 1987). Oda *et al.* (1991) studied the influence of the number of viable seeds per kilogram and the size of the seeds on the percentage of albino and abnormal plantlets. This study used *E. grandis* seeds collected at different times of the year and the seeds were classified into three groups (<0.50 , $0.59\text{--}0.71$, >0.71 mm). The results demonstrated that larger seeds were less likely to produce albino or abnormal plantlets and suggested that the production of small seeds could be linked to self-pollination.

Suzano (1994a) evaluated the behavior of different progenies of *E. grandis* with respect to seed vigor and initial plantlet growth, looking for possible links between these variables and the quality of the sapling and the future forest. The seeds of six progenies from the clonal seed orchard (second generation) were divided into two groups, >0.59 mm but smaller than 0.71 mm and >0.71 mm. The germination efficiency, SEI and the height of the plantlets at 32 and 40 days after seeding were evaluated. Differences between the progenies were demonstrated, thus during thinning the plantlets that have higher SEIs and faster initial growth will be preferentially

represented in the final product from the nursery. In this way, when breeding populations and commercial plantations are formed, not all of the progenies are equally represented, thus resulting in lower genetic variability, due to the reduction in the effective population number, and failure to achieve the expected results.

1.2.10 Quality of the seedling for planting

The selection of seedlings in the nursery by height is one of the parameters used to assess quality. The advantage of this selection is to form more uniform lots with a better use of the seedlings in the field (Coelho, 1984). According to the author, the practice of sapling selection in the nursery is a controversial question. Some authors state that a certain time after planting, the forest presented a more homogenous development even though the seedlings from the nursery were not selected. However, other studies report that the selection of taller seedlings give rise to taller trees. The removal of defective seedlings or seedlings with low vigor is, however, necessary. For example, of the total number of seedlings produced in the nursery by Companhia Suzano de Papel e Celulose, 20% were considered as abnormal, those presenting defects such as bifurcations and loss of vigor. Part of these abnormalities could be explained by different degrees of endogamy in the seed production plantation.

Coelho (1984) evaluated the silvicultural behavior of *E. grandis* seedlings up to 1-year old, based on seed, plantlet, and sapling size. The author observed that selection by size of the seedling had highly significant effects on height and diameter, suggesting that the selection for this species by seed or seedling should be encouraged in order to obtain trees with better growth qualities. Various studies demonstrate that the selection of seedlings can enable an initial gain in height, but with time this difference is reduced or disappears (Donald, 1976; Balloni *et al.*, 1978; Morais and Brune, 1983; Suzano, 1994b).

In this way, the selection of seedlings has an effect on the formation of commercial plantations where all the progenies do not participate in equal quantities, thus the genetic variability could be reduced due to the reduction in the size of the effective population.

1.2.11 Interaction genotype \times environment (G \times E)

Zobel and Talbert (1984) stated that when the tests are carried out at the same location, any effect is limited only by the genotype. This fact has two consequences: (a) the heritability could be overestimated, resulting in overestimation of the expected gains when the material is planted in an untested environment and (b) the genotypes selected in one environment may not be the best in other environments resulting in a reduction in the genetic gain. The authors also suggested that the G \times E interaction affects the strategy in forestry breeding programs as seen by tree mortality and/or reductions in growth.

Various studies have reported that stability is genetically controlled (Barriga, 1980; Torres, 1988). Kageyama (1980) evaluated the genetic variation in *E. grandis* (origin Coff's Harbour, Australia) generated by open-pollination in five locations: Agudos, Anhembi, Brotas, Lençóis Paulista, and Resende (SP, Brazil). The evaluation characteristics were as follows: form of the tree trunk, DBH, and height at 2-years-old. The effect of the location, significant on all of the characteristics, reflected in the reduction in heritability (at the level of the location, individual plants, mean of the families, and within the families) and, therefore, in the selection for the locations as a group. The same tendency was observed by Pinto Jr. (1984) in progenies of *E. urophylla* S.T. Blake from Island of Flowers (Indonésia), using conjugated origin testes and locations in four Brazilian states, Aracruz (ES), Anhembi (SP), Bom Despacho (MG), and Planaltina (DF).

Mori *et al.* (1986) estimated the genetic parameter for *E. saligna* from three locations (Itatinga (ACS); Areia Branca (PSC); and Salto (PS)) and planted at three test sites: General Câmara (RS), Brotas (SP), and Bom Despacho (MG). The characteristics evaluated were DBH, height, and cylindrical volume at 3-years-old. The coefficient of heritability when analyzed together was inferior to the majority of the coefficients obtained by test location, demonstrating losses in heritability because of the progeny \times location interaction. The losses in the selection due to this interaction were estimates at up to 88.3% for cylindrical volume.

Mori *et al.* (1988a) studied the progeny \times location interaction in 30 seven-years-old progenies of *E. urophylla* generated by open-pollination from the Island of Flowers (Indonesia) at four locations: Aracruz (ES), Belo Oriente (MG), Bom Despacho (MG), and Grão Mogol (MG). The values of the mean heritability (heritability coefficients at the plant level, progeny mean, and within the progenies) for the four locations were superior to the values obtained when the data was analyzed together, demonstrating the great effect of progeny \times location interaction. The losses in genetic gain due to the progenies \times location interaction for the cylindrical volume, DBH, and height, were 26.73%, 15.74%, and 8.14%, respectively. The authors compared the genetic gains (%), using the progeny mean of the cylindrical tree volume and three improvement strategies: multiple populations with selection of progeny for each location; the selection of individuals with a greater capacity to adapt to the study location, stable selection; traditional selection not considering environmental difference and the progenies \times location interaction. For this comparison, a selection proportion of 1:6 between progenies was used, which made possible the selection of progenies predictably more productive (selection of 5 progenies from 30). The genetic gains in percentage are shown in Table 2.

Carvalho (1989) evaluated the G \times E interaction in 50 clones of *E. grandis*, in the region of São Mateus (ES) in three traditionally reforested areas, using the following genetic parameters: heritability, standard deviation from the estimate of heritability, coefficient of genetic variation, and the quotient between genotypic variation and the coefficient of experimental variation, calculated using the measurable parameters DBH, height, cylindrical volume, and wood basic density. It was observed that the estimated heritability values were relatively high for all the measured characteristics when considered at each location. When the data was analyzed together, there was a general decrease for all the characteristics involved in growth (DBH, height, and volume), and less pronounced for basic density. Van Wyk *et al.* (1989) tested the stability of 31 hybrid Eucalyptus clones at 10 locations in South Africa, observing that many clones were stable for tree height. According to the authors, the results indicated that the selection of clones

Table 2 The genetic gains expressed in percentage (%) for the three strategies and the four locations

Strategy	Aracruz (ES)	Belo oriente (MG)	Bom despacho (MG)	Grão mogol (MG)	Mean
Multipopulation	18.81	10.18	14.18	26.10	17.32
Stable	5.09	0.79	10.72	13.25	7.46
Traditional	1.15	1.93	1.09	1.94	1.53

should be cautious since the behavior of each clone is location specific.

Cruz and Regazzi (1994, 2001) discussed the effect of the $G \times E$ interaction on the prediction of selection gains obtained using a particular improvement strategy. The authors presented situations in which it had been desirable to make gain predictions. These studies demonstrated that the effects of the $G \times E$ interaction should be considered in breeding programs, since it is possible that losses in the expected gains could occur in the selection of genotypes. According to Mori *et al.* (1988a) the $G \times E$ interaction, when badly administered, could result in a reduction of expected gains making it difficult for the breeding program to achieve its goals. The authors suggested, in order to minimize losses, a more adequate multipopulation strategy is necessary that considers the specificity of the genetic material for particular environmental conditions, through the selection of individuals more adapted and productive for each ecological region.

A genetic improvement program should have well-defined strategies, planned for short- and the long-term objectives, in order to obtain genetic material improved for the desirable characteristics. This material should guarantee the sustainability of commercial plantations and the continuity of the improvement program through the selection of advanced generations of trees and superior clones. The breeder should be acquainted with the factors that could reduce the expected genetic gains and how to intervene in the improvement strategies to minimize these losses.

1.3 Application of Molecular Markers in Eucalypt Breeding

The success of a breeding program depends on the genetic resources, which are being explored, the selection procedures, and the strategy used. There are numerous examples of successful Eucalypt

breeding programs throughout the world. The average Eucalypt productivity has been improved in three decades from $12 \text{ m}^3 \text{ ha}^{-1} \text{ year}^{-1}$ in the 1960s, to a current value of $60 \text{ m}^3 \text{ ha}^{-1} \text{ year}^{-1}$. The current performance has been reached because of applied silvicultural research and especially the breeding programs using high performance clones with fast growth, excellent wood quality, rusticity on poor soil, and resistance to diseases and pests.

The success of the breeding programs depends on the ability to distinguish heritable and environmental factors. Genetic markers are heritable when associated with the characters of interest and can increase the efficiency of selection. The segregation analysis of molecular markers permits the construction of genomic or linkage maps, to estimate gene frequency, especially useful to characterize the population gene diversity and germplasm in breeding programs for the genetic conservation of Eucalypts (Mori, 1993). Paternity tests and the study of mating system of different Eucalypt species have contributed to obtain superior clones in breeding programs (Camargo, 2001).

A genetic marker is a character capable of detecting differences between two or more individuals or organisms, be able to distinguish progenitors and progenies, and should present a series of attributes such as high level of polymorphism, stability in different environments, detection of high numbers of unlinked loci and of simple inheritance. In the following sections will be present the main types of molecular markers as well as their main applications in Eucalypt breeding programs.

1.3.1 Application of molecular markers in breeding programs

The selection of Eucalypt phenotypic characters for commercial purposes is time consuming because of the time taken to make field evaluations. One way to shorten this time is the use of molecular

markers. Various types are appropriate for use in Eucalypt breeding programs and some examples are given below.

1.3.1.1 Characterization of genetic diversity

The characterization of gene diversity in breeding programs is very important for researchers. Molecular markers are very useful to study the structure of populations, families, clones, cultivars, and also to discriminate gene pools from different populations.

Polymorphism based upon isoenzyme loci was studied in populations of *E. urophylla*, *E. grandis*, and *E. saligna* to develop tests for discrimination of interspecific hybrids from contaminants. Mori *et al.* (1996) concluded that the *Est-1*, *Est-2*, and *Idh-1* loci were useful for the purpose because some alleles were present in a population and absent in others and vice versa. Clones and progenies of five *E. grandis* subpopulations were analyzed by isoenzyme loci observing that the average inbreeding (*f*) was 0.08 and outcrossing rate (*t*) was 0.88. Much of the genetic diversity was within the subpopulations and there was practically no diversity between subpopulations ($F_{ST} = 0.011$) (Mori and Kageyama, 2001).

Sixty-nine progenies were analyzed representing one open-pollinated family of *E. urophylla* trees. RAPD markers allowed the identification of 72 loci that were analyzed using Jaccard's coefficient, generating matrices of genetic distances. The genetic distances between individuals were 0.40 through 12 groups. The progenies also showed different bark patterns, allowing the establishment of distinct groups. However, the groups based on genetic distances using DNA analysis did not correspond of those based on bark pattern (Pigato and Lopes, 2001).

A total of 44 natural hybrids of Eucalyptus, cultivated in central Brazil were analyzed. The RAPD markers presented efficient discriminating power, determining a mean genetic distance of 54% among them and genetic divergence from 24% to 73%. This demonstrated that there is a wide genetic base among individuals, which is desirable in breeding programs. Clustering analysis established by UPGMA (Unweighted Pair Group Method with Arithmetic mean) method, using 80% as a cut off criterion for the total genetic

distance, established nine distinct groups with average genetic divergence above 60% (Caixeta *et al.*, 2003).

The study of genetic diversity among trees is an important stage of any breeding program that targets the exploration of heterozygosis. The prediction of heterozygosis has been extensively used in Eucalyptus to obtain better hybrid combinations. In a study using 40 *E. grandis* and *E. urophylla* trees (two 10 × 10 circulate partial diallel crosses) were analyzed for their genetic diversity. The crosses were produced in a previous study based on the tree diversity using RAPD markers. Seventeen microsatellites amplified 75 allelic forms and gave a heterozygosis value of 26.1%. The genetic distance varied from 10% to 100%, whereas the mean genetic distance was 64.6%. The cluster analysis for the 40 trees showed high diversity and formed two groups (one for each species), although some genotypes were outside their species-specific group. In comparison with groups formed by the RAPD markers, microsatellite markers were more efficient in discriminating species. However, the correlation values among RAPD and microsatellite markers were low and negative. Microsatellite markers were efficient to discriminate trees of *E. grandis* and *E. urophylla* (Muro-Abad *et al.*, 2005).

1.3.1.2 Fingerprinting

The characterization and identification of individuals are important procedures in plant breeding. Rocha *et al.* (2002) used RAPD and simple sequence repeat (SSR) markers to obtain an exclusive fingerprint for 15 genotypes of Eucalypt hybrids with high potential for vegetative propagation used in breeding programs. Those two molecular techniques produced a set of markers that allowed an accurate identification of all genotypes. The RAPD procedures were also used by Pimenta *et al.* (2001) to obtain information on origin, genetic distance, and relationship among clones.

Hybridization between three species of *Eucalyptus* in the Series *Curviptera*, *E. macrocarpa*, *E. pyriformis*, and *E. youngiana* was investigated using RAPD markers. The dendrogram based on genetic similarities showed the relative proximity and distance among the individuals. Two clusters were identified by the UPGMA dendrogram.

One of them included all of the *E. macrocarpa* genotypes and also one of *E. macrocarpa* hybrid. The other included all of the *E. youngiana* and *E. pyriformis* genotypes and their hybrids (Neaylon *et al.*, 2001).

1.3.1.3 Quantitative trait loci (QTL) mapping

Most Eucalyptus breeding programs have used interspecific hybridization, making it possible to capture nonadditive genetic variance. Propagating genotypes via vegetative propagation greatly enhanced the possibility to use genetic linkage maps for accelerating breeding programs by marker-assisted selection (MAS) and recombination (Grattapaglia and Sederoff, 1994).

Linkage maps were constructed mainly by RAPD dominant markers (Verhaegen *et al.*, 1997), amplified fragment length polymorphism (AFLP) dominant markers (Gaiotto and Grattapaglia, 1997), and SSR co-dominant markers (Brondani *et al.*, 1998). The maps could identify genomic regions in eucalypts with significant effects on expression of economically important characters. Various characters were studied by QTL analysis, such as, characters associated to eucalypt rooting (Marques *et al.*, 2002), insect resistance (Shepherd *et al.*, 1995), plant growth (Squilassi and Grattapaglia, 1998), and *Puccinia psidii* rust resistance in *E. grandis* (Junghans *et al.*, 2001). There are also studies for different eucalypt species and cultures in which few loci with major effects controlling a relatively large proportion (from 10% to 40%) of total phenotypic variation for quantitative characters of silvicultural importance, such as, wood volume and wood density were detected.

Squilassi and Grattapaglia (1998) mapped QTLs in eucalypts for wood volume by RAPD markers, using linkage disequilibrium on selected progenies. The study showed that the MAS was efficient to select through the family mean level; however, it was not efficient at the individual level.

Gion *et al.* (2001) studied 201 full-sib families from interspecific hybrids between *E. urophylla* and *E. grandis* for eight genes involved in the lignin biosynthesis (PAL (phenylalanine ammonia-lyase), COMT1 (caffeate/5-hydroxyconiferaldehyde O-methyltransferase 1),

COMT2, 4CL (4-coumarate:coenzyme A ligase), C4H (cinnamate 4-hydroxylase), CCoAOMT (caffeoyl coenzyme A O-methyltransferase), CAD2 (cinnamyl alcohol dehydrogenase 2), and CCR (cinnamoyl-coenzyme A reductase)) and three Myb transcription factors. The genes were mapped using the single strand conformation polymorphism (SSCP) technique. These genes were located on the two parental genetic maps constructed with polymerase chain reaction (PCR)-based markers. The lignin monomeric compositions (S/G ratio) were obtained using the thioacyolysis method and the QTL analysis for S/G ratio was performed using the interval mapping procedure. Several regions controlling part of the variation were identified, showing that multipoint estimates of the total variation explained through the QTL were 38.0% and 18.5% for *E. urophylla* and *E. grandis*, respectively. The study shows that it should be possible to follow the manipulation of lignin quality in breeding programs using molecular markers.

1.3.1.4 MAS

Some studies were carried out using isoenzyme markers to allow earlier selection of superior genotypes. Menck (1996) studying the acid phosphatase isoenzyme in clones of *E. grandis* cultivated *in vitro* found a correlation between superior genotypes for growth characters and those for efficiency by the use of phosphorous. The author also observed correlations between superior genotypes on the field and higher activities of acid phosphatase enzyme.

The transfer of disease resistance alleles in plants can be expedited by the use of DNA markers. If the markers are tightly linked to the resistance alleles they can be used for MAS. One effective use of MAS is found in the process of pyramiding resistance alleles. The use of MAS is based upon the principle that a gene or a block of genes is associated with a molecular marker of easier identification, making the selection for that marker more efficient than the selection for the phenotypic character. MAS in eucalypt has focused mainly on wood growth, which is an important commercial character, easily measured but of low heritability.

Experimental full-sib families of *E. grandis* and *E. urophylla* were used to evaluate the comparative

efficiency of selection based on molecular markers associated with a favorable QTL and the regular phenotypic selection for diameter at breast height (Squillasi and Grattapaglia, 1998). The authors did not study all possible crosses, evaluating only the maternal QTL allelic contribution, because an effective assessment of MAS in eucalypt depends on experiments where the phenotypic data are gathered at adequate ages and QTL information is preferentially available for all progenitors involved in the pedigree (Squillasi and Grattapaglia, 1998).

Using the BSA (bulked segregant analysis) procedure, Bortoloto (2006) developed a SCAR (sequenced characterized amplified region) marker to detect the flowering time region on *E. grandis* map. The marker presented linkage to the EMBRA 7 (Brondani *et al.*, 1998) microsatellite marker on a paternal map. The author also detected linkage of the *EgLFY* flowering gene to the EMBRA 6 (Brondani *et al.*, 1998) microsatellite marker indicating the region for flowering control.

1.3.1.5 Recombination of genotypes and seed orchard

Eucalyptus species are widely used for planting through tropical and subtropical regions of the world and they are predominantly outcrossing, highly heterogeneous, and genetically diverse (Moran and Bell, 1983). Using microsatellites and AFLP markers, Zelener *et al.* (2005) studied six provenances and 37 selected half-sib families of *E. dunnii* to make a selection to establish a seed orchard. The estimated genetic differentiation showed low values among provenances ($\theta_P = 0.026$) and high values among families ($\theta_S = 0.174$). A high proportion of the total variation observed within families suggested that the orchard design should be based upon individual or family selection rather than provenance selection.

A *E. dunnii* breeding population of 46 provenances from Australia and selected for fitness through subtropical and cold environments was screened by AFLP and microsatellite markers to estimate the genetic diversity. The markers presented no significant differences between the original breeding population and the selected genotypes of seed orchard confirming that the seed orchard can be established with a limited number

of individuals without problems of inbreeding (Poltri *et al.*, 2005).

Microsatellite markers were used to genotype potential pollen donor and maternal progenies from a *E. globulus* seed orchard in Chile and an *E. grandis* seed orchard in Uruguay. The resulting data were used to infer the most likely pollen parents for the seed from each seed orchard. The estimated distances from maternal tree to the most likely male parent served as the data set basis to model the pattern of gene flow in both orchards. The results indicate that the pollen dispersal may reach distances as far as 300 m or more (Russell *et al.*, 2001).

1.3.1.6 Mating system

Eucalypts present hermaphrodite flowers making possible selfing and outcrossing rates at different levels. Different authors have observed that eucalypts present a model of mixed mating, predominantly by outcrossing, however inbreeding can occur by selfing and crossing amongst relatives.

Moran and Brown (1980) studying a population of *Eucalyptus delegatensis* by isoenzymes, observed an average outcrossing rate of 0.77, with differences occurring between young ($r = 0.66$) and adult ($r = 0.85$) plants. Through time, the populations change and usually there is a tendency for endogamous individuals to die, increasing the level of heterozygosity in the population. Moran *et al.* (1989) studying a seed orchard of *E. regnans* observed an outcrossing rate ($r = 0.91$) higher than that of the natural population ($r = 0.74$). The lower rate of outcrossing in natural populations could be due to inbreeding between physically close relatives. In a seed orchard there are no relatives and the inbreeding occurs via selfing. Mori (1993) investigating a seed orchard of *E. grandis*, also using isoenzymes found an outcrossing rate of 0.88.

Patterson *et al.* (2001) determined the outcrossing rates at two positions on the tree: the top and the bottom of the canopy in *E. globulus*, in a remnant of a native stand in southern Tasmania using isoenzyme markers. In trees previously determined to have high levels of self-incompatibility, outcrossing rates were high at both, the top and bottom of the canopy (from 0.87 to 0.99). In contrast, the outcrossing rates

in self-compatible trees were significantly different in both positions of the canopy: lower at the bottom (from 0.27 to 0.66) than the top (from 0.74 to 0.90). These results were of particular significance to collection of open-pollinated seed for breeding or deployment, where unfortunately, the most accessible seed may also be the most inbred.

Mori *et al.* (2004) studying *E. grandis* progenies by microsatellite markers observed an outcrossing rate of 0.67 indicating that the species shows crossing among relatives and selfing.

1.3.1.7 Diagnosis of disease resistance

Eucalypt rust, caused by *P. psidii*, is one of the most serious diseases in Brazil and considered to be the most serious threat to eucalypt plantations worldwide. Junghans *et al.* (2001) analyzed the number of sorus and pustule size to characterize rust severity on *E. grandis* seedlings which were further screened with RAPD markers. One of the markers (AT/917) showed complete cosegregation with *Ppr-1* (*P. psidii* resistance, gene 1). All the resistant plants showed the marker, while no susceptible plants had this marker. The AT9/917 sequence was used to obtain specific primers (SCAR), which will be used for screening clones in an *E. grandis* genomic library.

Using microsatellite markers, Mori *et al.* (2004) also studied rust resistance character in progenies of *E. grandis*. Nei's genetic distance varied up to 0.400 and the index of gene diversity varied from 0.383 to 0.713, having an average of 0.587.

1.3.1.8 Analysis of paternity

It is very common to use molecular markers to check the paternity of a superior elite tree obtained by open-pollination. The analysis of paternity is especially important to determine the other parent contributing to the genotype with superior gene combination.

Estimates of the level of multiple paternities correlated with outcrossing within and between fruits in a pre outbred population of the bird-pollinated mallee, *Eucalyptus rameliana*, were made by Sampson (1998) using six isoenzyme loci. The correlation of outcrossing paternity (r_p) was

positive and significant within fruits (0.26) and the effective number of mates for a single fruit was estimated to be 3.85. The specialization of floral structure and phenology in *E. rameliana* for bird pollination has probably contributed to correlation of paternity within fruits because there are fewer male parents available at any one time when compared to the mass-flowering species.

Paternity analysis using microsatellite markers was conducted on a *E. nitens* seed orchard in Victoria, Australia. An average of 40 seeds per clone were germinated and screened for paternity using the four loci. Paternal contribution varied among clones, suggesting that panmictic pollination was not occurring, probably due to differences in flowering time and flower numbers between the clones such that each clone was subjected to a different pollen pool. Distance between clones was another important factor influencing paternal contribution (Grosser *et al.*, 2001).

1.3.1.9 Comparison of breeding generations of *Eucalyptus*

Pigato and Lopes (2001) studied the diversity and the genetic distances in four generations of *E. urophylla*, which provided data to help guide the breeding program. The initial base population was introduced by seeds collected in Indonesia (P_0 generation). In the subsequent segregating generations originated by open-pollination, recombinations were designated as P_1 , P_2 , and P_3 . One hundred and seventy four individual trees representing the four generations were analyzed. The RAPD technique allowed the identification of 86 positions analyzed using the Jaccard Coefficient. The genetic distance from P_0 generation was 0.33, 0.34 from P_1 , 0.40 from P_2 , and 0.38 from the P_3 generation. The genetic distances between individuals increased in relation to the base population, being 0.15% from P_1 generation, 18.93% from P_2 , and 13.31% from P_3 , showing an increase in genetic diversity in the advanced generations, despite selective processes. Genetic diversity of 14 populations of *E. grandis* were studied by Mezzena (2003) utilizing microsatellite markers. The populations were at different levels and breeding generations. The inbreeding coefficients within the populations

were very similar ($f = 0.16$). The author observed a little loss of heterozygosity from F_1 ($H_o = 0.64$) to F_2 ($H_o = 0.60$) breeding generations.

2. DEVELOPMENT OF TRANSGENIC EUCALYPTUS

2.1 *In Vitro* Culture in Eucalypts as a Prelude to Genetic Transformation

From the agribusiness point of view, eucalypts are important in many aspects. Essential oils can be extracted from the leaves; tannins from the bark; and wood, methanol, charcoal, and cellulose for paper production can be extracted from the trunk. Hence, it is not strange that millions of hectares are planted in the world. Currently, Brazil has the biggest collections of *Eucalyptus* spp., even bigger than Australia and Indonesia (Ferreira, 1992). In addition, this genus has species with various interesting attributes such as fast growth, adaptation to poor soils, fertile hybrid formation, and capacity to produce roots from stump sprouts (coppiced).

Commercially, *Eucalyptus* propagation has been traditionally done by seed, but, the cellulose and paper industry has stimulated research to attempt clonal multiplication (Xavier and Comério, 1996; Rosse *et al.*, 1996), to optimize field production, reduce costs, and to achieve better genetic gain (Thorpe and Harry, 1990). Ikemori *et al.* (1994) showed that pulp and cellulose production was significantly higher in cutting cloned forests ($10.9 \text{ t ha}^{-1} \text{ year}^{-1}$) than in unimproved seedling forest ($5.9 \text{ t ha}^{-1} \text{ year}^{-1}$). However, the propagation via rooted cuttings offers difficulties such as loss of rooting capacity in the adult trees (Brune, 1982; Burger and Lee, 1987) and plagiotropic, a bushlike growth pattern (Durand-Cresswell *et al.*, 1985; Flynn *et al.*, 1990). *Eucalyptus* spp., despite the fact that many species can propagate by cutting due to the presence of an epicormic bud at the base of adult trees others, such as *E. regnans*, *E. nitens*, *E. fraxinoides*, and *E. deglupta*, are recalcitrant (Hartney, 1980).

In cloning, tissue culture has been used for several years as a tool to propagate uniform and selected material with major commercial value (Karnosky, 1981; Haissig *et al.*, 1987; Hartmann *et al.*, 1990; Kozai and Kubota, 2001). On

the other hand, the development of breeding programs with woody plants for additive or nonadditive genetic variation has been too slow. Therefore, tissue culture has been effective in these programs, aiming to diminish the time to obtain intra- and interspecific hybrids. Recently, *in vitro* culture has contributed efficaciously to the research on biolistic or *Agrobacterium tumefaciens* transformation with the objective to reach new genetic commercial arrangement for forestry at short, medium, and long terms (Rochange *et al.*, 1995; Machado *et al.*, 1997; González *et al.*, 2002).

There are many reviews reporting *in vitro* techniques showing morphogenesis either via organogenesis or embryogenesis to obtain whole plants in *Eucalyptus* spp. (Hartney, 1982; Durand-Cresswell *et al.*, 1985; LeRoux and van Staden, 1991a; Sita, 1993). In this context, problems with genotype, contamination, and phenol oxidation have been reported as serious challenges to be overcome. For the time being, problems with somaclonal variation and genetic stability (Tibok *et al.*, 1995; Azmi *et al.*, 1997; Rani and Raina, 1998) or vitrification (Bunn, 2005; LeRoux and van Staden, 1991b) have not been cited as important drawbacks.

Tissue culture is a strong biotechnological tool for micropropagation with potential large-scale propagation of *Eucalyptus*. Having elite material with determined degrees of genetic gain so as to replace seeds by cloned propagation, with low cost and high quality products for wood and cellulose and competitiveness is the basic premise of any company. Here we attempt to review the use of *in vitro* tissue and organ cultures to produce *Eucalyptus* clonal forestry, showing different experimental procedures according to the literature available by the author.

2.1.1 The explants

Table 3 shows that different explants that have been utilized to initiate *Eucalyptus* tissue culture and that the use of nodal segments from elite adult plants is more frequent. Although contamination has been recorded (Fossard *et al.*, 1977; Durand-Cresswell *et al.*, 1985), this has not been described as a problem in *Eucalyptus*, even if explants from field or simply surface-sterilized by HgCl_2 or NaOCl was used (Figure 3) (Rao

Table 3 Summary of some protocols for *Eucalyptus* micropropagation

Species	Explant	Basal medium	Growth regulators (μM)	Organogenesis (via)	Rooting (μM)	References

and Venkateswara, 1985; Gupta and Mascarenhas, 1987; Bennett *et al.*, 1994). However, it seems that this cannot be generalized since 70% of *in vitro*-inoculated nodal explants from forest trees show contamination, while greenhouse nodal fragments remained virtually contamination-free (Fossard *et al.*, 1977). On the other hand, with respect to surface sterilization of explants, most reports show use of NaOCl or HgCl₂ with varying periods from 10–20 min for NaOCl, and from 5–15 min for HgCl₂. Concentrations varied from 0.12% to 9.0% of NaOCl and from 0.02% to 0.1 % for HgCl₂. Prior to the treatments, fungicide has sometimes been used (LeRoux and van Staden, 1991a, b).

Also, the material sometimes was thoroughly rinsed with tap water and detergent (Gupta and Mascarenhas, 1987; Das and Mitra, 1990), before sterilizing with HgCl₂ or commercial bleach.

Ca(OCl)₂ is an energetic oxidant, with low phytotoxicity, similar to NaOCl. However, due to its powder formulation and the need to be filtered, few studies have used it as a surface sterilizer for the inoculation material. In these cases, concentrations varied from 5% to 7% for 5–20 min (Cresswell and Nitsch, 1975; Fossard *et al.*, 1977; Trindade and Pais, 1997).

Other chemical substances against bacteria and fungi have rarely been mentioned in *Eucalyptus*

Figure 3 Seedlings of *E. grandis* × *E. urophylla* approximately 14-day-old in SP medium, seeds surface disinfected with NaOCl (9%) for 10 min, showing hypocotyls, cotyledons, roots, and contamination free. Growth conditions: $24 \pm 2^\circ\text{C}$, 16 h photoperiod, and photosynthetic photon flux density at $50 \mu\text{m}^{-2} \text{s}^{-1}$

studies, besides ethanol and H_2O_2 . Alkydimethylbenzalkonium chloride, ADBAC for example, was a product rarely cited (Bunn, 2005), and biocide-type isothiazolones such as PPM (Niedz and Bausher, 2002) were not used in Eucalyptus micropropagation. The later is heat stable, with a broad spectrum against plant contaminants (Compton and Koch, 2001). Physical methods such as the use of hot water and UV light have practically not been mentioned in explant sterilization procedures for Eucalyptus.

In general, phenolic oxidation is mostly inconvenient in *in vitro* cultures (Prieto *et al.*, 2005) often demanding the use of various alternative substances to overcome it (Ziv and Halevy, 1983). Changes in peroxidase activity and level of phenolic compounds were showed by Arezki *et al.* (2001) in *E. camaldulensis*.

In Eucalyptus, browning has hindered the establishment of some protocols such as those related to protoplasts (Teulières and Boudet, 1991), cell suspension (Teulières *et al.*, 1989; Barrueto *et al.*, 1997), nodal explants from adult trees (Rao, 1988; Das and Mitra, 1990), or floral origin (Warrag *et al.*, 1991), being necessary the use of antioxidant substances such as polyvinylpyrrolidone and ascorbic acid in several cases, or adsorbents of toxic substances such as

activated charcoal. Other methods reported the use of periodic subcultures, initial dark period, or using explants from established shoot cultures (LeRoux and van Staden, 1991a, b).

2.1.2 Shoot multiplication and hormone treatment

Once the explants have been established in a basal medium, multiplication follows via organogenesis or embryogenesis. Usually the basal medium used in this phase is an extension of the medium used previously, frequently a Murashige and Skoog (MS) medium (Table 3). Salt and vitamins from the MS nutrient medium have been used in their original form (Rao, 1988; MacRae and van Staden, 1990; Bennett *et al.*, 1994; Yang *et al.*, 1995) or with modifications (Hartney, 1982; Barrueto *et al.*, 1999) depending on the purpose (induction of organogenesis or somatic embryogenesis) and the genotype used.

Auxin and cytokinin have been useful to obtain *in vitro* plants from basal medium at different levels. Calli have been obtained with $2 \mu\text{M}$ thidiazuron (TDZ) using juvenile material from a *E. grandis* × *E. urograndis* hybrid (using cotyledon, hypocotyls, and cotyledonary

node), and plants were obtained when these calli were submitted to different concentrations of 6-benzylaminopurine/ α -naphthalene acetic acid (BAP/NAA) or Zeatin/NAA. The best results were obtained with Zeatin: 5.0 μ M and NAA 0.5 μ M, respectively, using cotyledonary node explant (Barrueto *et al.*, 1999).

Calli were also obtained with hypocotyl juvenile material from *E. grandis* using a combination of 21.5 μ M NAA and 4.6 μ M kinetin (Kin) and organogenesis was observed when the material was transferred to a hormone-free medium (Warrag *et al.*, 1991). Callus induction was also observed in *E. citriodora*, from cotyledons and hypocotyls submitted to different auxins: IAA (indole-3-acetic acid), NAA, 2,4-D (2,4-dichlorophenoxyacetic acid) (range: 0.1–5.0 mg l^{-1}) plus coconut milk (15%); however, organogenesis occurred when calli were placed in 2.7 μ M Zeatin and 1.1 μ M IAA (Sita, 1979). According to the same author, calli from leaves originated from mature plants induced with 27 μ M NAA and 28 μ M IAA, but no organogenesis was observed. Organogenesis was observed in *E. urophylla*, from hypocotyl explants when MS was supplemented with several NAA/BAP concentrations, showing better results with NAA at 1.1 μ M and BAP at 0.88 μ M (Tibok *et al.*, 1995); however, shoot production of *E. grandis* \times *urophylla* was also effective, at 13.7 per explant with NAA/BAP at 0.54 μ M and 0.44 μ M on apical shoots and auxiliary bud, respectively (Yang *et al.*, 1995).

At low concentrations (NAA 0.54 μ M and BAP 0.9 μ M), shoot multiplication from nodal explants of juvenile *Eucalyptus* of many species (*E. smithii*, *E. saligna*, etc.) showed good results (LeRoux and van Staden, 1991a, b). Using auxiliary meristems, shoots were also obtained with different genotypes of *E. tereticornis*, inoculated onto MS basal medium. Among the growth regulators tested, NAA/BAP/IAA at 5.3, 4.4, 1.1 (μ M), respectively, was more effective giving 32–45 shoots per explant. Repeated subculture in MS plus IAA 0.1 μ M and BAP 0.44 μ M, produced around 200 shoots per explant (Rao, 1988). With nodal segments from an 8–10-year-old *E. tereticornis*, 18–22 shoots per explant were achieved with modified MS supplemented with NAA 0.54 μ M and BAP 4.44 μ M (Das and Mitra, 1990). Low concentrations of growth regulators were also used with *Eucalyptus impensa* to obtain

shoot multiplication in half-strength MS medium plus BAP 2.5 μ M and Kin 2.5 μ M from shoot segments as explants (Bunn, 2005).

Regeneration competency from auxiliary and apical buds was observed in 20-year-old *E. citriodora*. This was achieved by incubating the explants at 15 °C for 72 h, and then incubating them in a liquid MS-2 media (120 rev min^{-1}). Five to eight shoots per bud developed. After this, individual shoots were transferred to solid MS-2. In this new condition, 10–15 shoots were obtained per explant (Gupta *et al.*, 1981). The MS-2 medium was supplemented with Kin 0.93 μ M, BAP 1.33 μ M, calcium pantothenate, and biotin (0.1 mg l^{-1} of each). According to the authors, it could be possible to get 100 000 viable plants per year from a single bud using this protocol.

Somatic embryogenesis was obtained with *E. citriodora* using NAA 16.13 μ M and zygotic embryos as a starting point. The basal medium (B5) was supplemented with sucrose 50 g (Muralidharan *et al.*, 1989). In a peculiar protocol, somatic embryogenesis was also described for *E. grandis*. This was obtained with leaves from *in vitro* seedlings using 2,4-D (2.3 μ M) for callus induction. Callus proliferation was reached in MS medium with 4 g l^{-1} of activated charcoal containing (μ M): 0.05 NAA, 0.44 BAP, and 0.27 gibberellin. However, additional study was mentioned for implanting large-scale production (Watt *et al.*, 1991). In conclusion, low concentrations of BAP and NAA seem to be more effective for *Eucalyptus* shoot multiplication under a wide range of experimental conditions (Table 3); however, these wide experimental conditions, basically, included *Eucalyptus* solid cultures and not liquid cultures, probably because liquid medium can cause vitrification—hyperhydricity (Monsalud *et al.*, 1995).

2.1.3 Shoot elongation

Usually, shoot elongation has been obtained using a half-strength medium. In *E. camaldulensis*, regenerated shoots were transferred to quarter strength B5 basal medium plus NAA 0.05 μ M (Kawazu *et al.*, 1996). In *E. grandis* \times *E. urophylla* shoot elongation was more efficiently obtained with MS medium containing half-strength potassium nitrate and sucrose (Yang *et al.*,

1995). On the other hand, the elongation of shoot clusters may be mediated with gelling agents. In *E. grandis*, the MS medium containing Gelrite plus a combination of NAA/BAP/GA (μM): 0.05, 0.44, and 0.27, respectively, improved shoot-cluster elongation (MacRae and van Staden, 1990). In contrast, optimum shoot elongation of *Eucalyptus torelliana* and *E. camaldulensis* was achieved with solid and liquid MS-2 media, respectively, using Kin/BAP: 0.23 μM and 0.44 μM , respectively (Gupta *et al.*, 1983). In addition, *E. grandis* shoot elongation was promoted in MS plus gibberellic acid 2.7 μM prior to rooting (Sita and Rani, 1985).

2.1.4 Rooting

The formation of roots from excised shoots in one-fourth strength MS containing IAA 10 μM with no cytokinin was reported by Hartney (1982). In addition, shoots of *Eucalyptus sideroxylon* from modified MS (half-strength salts, full-strength organic constituents) rooted with 10 μM IBA (indole-3-butyric acid). IBA was more effective than NAA in adult or coppice tissues (Burger, 1987). Differences in rooting between juvenile and old tree material were also noted in *E. citriodora* (Gupta *et al.*, 1981). In general, this is a physiological characteristic of woody species that *in vitro* regeneration and rooting ability decrease with age. For *E. tereticornis*, the presence of IBA in the basal medium was essential for rooting, as well as the use of a dark period before the transfer of shoots to light (Das and Mitra, 1990). A period of 72 h in darkness, prior to a 16 h photoperiod along with hormonal treatment, was used to root four *Eucalyptus* genotypes, giving different rooting ability, inclusive, deficient rooting was observed in *Eucalyptus macarthurii* and *E. smithii*. In addition, these species also showed poor rooting from coppice cuttings (LeRoux and van Staden, 1991a). *Eucalyptus globules* showed better results when low concentrations of IBA (1.0–2.5 μM) were used and when NH_4NO_3 was removed from the root-induction medium (Bennett *et al.*, 2003).

Rooting of different clones of *E. globulus* was verified after different periods of rejuvenation using subculturing routines (Trindade and Pais, 1997). Root induction improved when riboflavin and choline chloride were included in the medium and boron was removed from the rooting medium.

The authors also reported that IBA dipping before transfer to the rooting medium improved the appearance of adventitious roots. Experiments with *E. grandis* \times *E. urophylla* using modified SP supplemented with IBA 2.5 μM for 5 days and transfer of shoots to a similar medium with activated charcoal (1 g l^{-1}) greatly improved rooting but resulted in little callus formation at the base of some shoots (Barrueto *et al.*, 1999).

Despite auxin being an important factor in root induction, care must be taken to avoid callus induction at the base of the shoots (Mehra-Palta, 1982; Rao, 1988; Cheng *et al.*, 1992). On the other hand, cytokinin is a critical component of the multiplication media, but inhibitory for the rooting media. However, subsequent adventitious root production in rooting medium was better when Kin was used during the last multiplication (Bennett *et al.*, 1994). As seen above, rooting is a highly clone-dependent characteristic, hence, one must be careful when testing or improving rooting conditions, especially with shoots from a mature tree, older the tree, smaller the rooting ability.

2.1.5 Temperature and light

In general, the culture conditions for *in vitro* Eucalyptus plant establishment were a constant temperature of $25 \pm 2^\circ\text{C}$ and a 16 h photoperiod, involving different ranges of photosynthetic photon flux density (PPFD) from cool fluorescent light bulbs (Rao and Venkateswara, 1985; Subbaiah and Minocha, 1990; Termignoni *et al.*, 1996; Sartoretto *et al.*, 2002; Bennett *et al.*, 2003).

2.1.6 Hardening plantlets

The transfer from tube to soil under greenhouse condition is an important step in the micropropagation process. Usually, intermittent mist or a plastic cover is required as well as plastic pots with sterile vermiculite and adequate natural or artificial light and temperature. When established, plantlets are transferred to polyethylene bags with a mixture of soil and sand. Survival is variable, but, usually high. Generally, a hardening protocol contains steps similar to those previously described with variation in the composition of the rooting substrate (inclusion of fertilizer, fungicide, etc).

Finally, the plants are taken to the field and their performance is evaluated in terms of survival, growth rates, and biomass production. On the whole, micropropagated *Eucalyptus* plants have the same appearance as their sources (Mehra-Palta, 1982; Gupta and Mascarenhas, 1987; Warrag *et al.*, 1989; LeRoux and van Staden, 1991a). Consequently, tissue culture techniques have been observed with great interest in agronomy, forestry, and ornamental plant production, due to the economic benefits of clonal propagation on a commercial level; however, the productivity of commercial clones can be reduced by viral infections, but culture of meristem tips is a good way to combat this (Rutledge and Douglas, 1988).

2.2 Genetic Transformation of Eucalypts

To maintain and sustain forest vegetation, conventional approaches have been exploited for propagation and improvement, but tree breeding efforts are restricted to the most valuable and fast growing species. However, such methods are limited with several inherent bottlenecks because trees are generally slow growing, long-lived, sexually self-incompatible, and highly heterozygous plants. Due to the prevalence of high heterozygosity in these species, a number of recessive deleterious alleles are retained within populations, resulting in high genetic load and inbreeding depression. This limits the use of traditional breeding methods such as selfing and backcrossing, and makes it difficult to fix desirable alleles in a particular genetic background (Williams and Savolainen, 1996). Thus, conventional breeding is rather slow and less productive and cannot be used efficiently for the genetic improvement of trees. To circumvent these impediments clonal or vegetative propagation has been deployed for recovering dominant, additive, and epistatic genetic effects to select superior genotypes. Plant tissue culture and genetic transformation methods offer an important option for effective multiplication and improvement of trees within a limited time frame. Biotechnological approaches for *in vitro* regeneration, mass micropropagation techniques, and gene transfer studies in tree species have been encouraging, particularly in the last decade. With these techniques, genetic engineering assumes additional significance, allowing introduction of

desired gene(s) in a simple step, for precision breeding of forest trees (Giri *et al.*, 2004).

Until recently, trees were considered to be recalcitrant for genetic transformation studies involving molecular techniques. The main obstacle for genetic transformation of trees is the regeneration of transformed plantlets. *Agrobacterium*-based genetic transformation is normally the main method used for developing transgenic trees. Further regeneration of plants from single cells is a requisite for *Agrobacterium*-mediated gene transfer to achieve homogenetically transformed plants (Giri *et al.*, 2004).

Choice of explants having competence for transformation and regeneration is a crucial factor. At this point in time efficient tissue culture techniques become the foundation for genetic transformation studies. In addition to the regeneration through organogenesis, somatic embryogenesis definitely offers the advantage of single cell regeneration and currently appears to be the most promising approach to introduce new genes into woody tree species (Giri *et al.*, 2004).

Despite the progress in recent years, challenges remain for the transformation of hardwood trees. Although elite individual of hardwoods such as poplar, eucalypts, and sweet gum can be maintained by vegetative propagation methods, genotypic variation in regeneration prohibits the inclusion of many genotypes in tree improvement programs. Even for the elite genotypes that are propagated for clonal deployment, transformation can be limited by *Agrobacterium* susceptibility or *in vitro* regeneration. At the moment hardwood transformation is largely limited to either the clones that are easy to transform and regenerate or juvenile materials that have higher regeneration and transformation potential. Maturation is another common problem. While seedling or juvenile tree explants are relatively easy to regenerate and transform, explants of mature trees tend to lose regeneration potential. Unfortunately, elite clones are selected from older trees with years of field performance data (Nehra *et al.*, 2005).

A limitation to the use of this technique lies in the general recalcitrance of eucalypts to transformation and poor regeneration capacity (Poke *et al.*, 2005). At this time, the stable transformation has only been successful in a small number of species including *E. camaldulensis*, *E. globulus*, *E. urophylla*, *E. grandis*, and *E. urophylla* ×

E. grandis hybrids (Mullins *et al.*, 1997; Ho *et al.*, 1998; Moralejo *et al.*, 1998; González *et al.*, 2002; Tournier *et al.*, 2003; Valerio *et al.*, 2003). These are predominantly laboratory studies. Field studies of transgenic eucalypts have been reported in the United Kingdom and Spain in 1995, in Portugal and South Africa in 1997, and Uruguay and Chile in 1997/1998 (Potts *et al.*, 2001) including field testing of glyphosate-resistant transgenic *E. grandis* (Llewellyn, 2000).

Despite the clear potential of genetic engineering for improving woody plants during the last 10 years, progress has been slow on *Eucalyptus*, which is still considered recalcitrant. In particular, regeneration and tissue culture is often very poor, probably due to the high concentration of phenolic compounds in the cells (Tournier *et al.*, 2003) or to low endogenous cytokinin content as shown by Azmi (1999). Regeneration capacity is even lower on a selective antibiotic-containing medium making it often impossible to recover transgenic shoots even when stable transformation is achieved (Serrano *et al.*, 1996; Sartoretto *et al.*, 2002).

2.2.1 Gene transfer

From a scientific point of view, the transfer of specific genes with a known function is very similar to classical breeding, but due to a restricted approach, the efficiency is increased. The prerequisites for gene transfer aiming at cultivar improvement are as follows:

- Availability of the trait to be transferred as cloned-DNA;
- Availability of a powerful transfer system; and
- Availability of a reliable regeneration system predominantly from a single transformed cell.

The last two points are solved in principle, although regeneration is still a problem. Regeneration is more an art than a science, particularly in transformation of *Eucalyptus* clones. However, recipes are available and, with sufficient trials and the use of a range of different genotypes, success should be achievable. Transfer studies are predominantly via *Agrobacterium*, as such transformations are more stable than microbombardment techniques during subsequent meiosis. Microbombardment has, however, the advantage that it can transform meristematic cells,

therefore the regeneration of plants is relatively easy to achieve. The most critical problem is still gene isolation. Most of these isolated genes are used in transformation experiments for basic research to elucidate biochemical pathways and add knowledge particularly in the field of metabolomics (Wenzel, 2006). Most of the patented genes available in the market, which are expected to give a determinant trait, have not been sufficiently tested in *Eucalyptus*. However, patented genes for specific traits in engineered plants have not generated improved commercial *Eucalyptus* clones, yet.

2.2.2 The use of biolistics in the genetic transformation of *Eucalyptus*

Microprojectile bombardment, which bypasses the problems associated with host specificity of *Agrobacterium* and regeneration systems, offers an alternative approach for the delivery of DNA into cells that are also competent for regeneration. Because the particle gun concept involves physical introduction of DNA into the cell, it potentially allows the transformation of any living cell, independent of its type or localization in the tissue (Sartoretto *et al.*, 2002).

Serrano *et al.* (1996) obtained stable transformation of *E. globulus* cells for the first time, using biolistic DNA delivery in zygotic embryos as the target material; however, no transgenic plants were regenerated. Sartoretto *et al.* (2002) reported a procedure for genetic transformation of calli from a *E. grandis* × *E. urophylla* hybrid using particle bombardment of calli derived from cotyledon and hypocotyl. However, the calli were unable to regenerate transgenic shoots, suggesting that the conditions suitable for regeneration are unsuitable for transformation and *vice versa*. In spite of some interesting advances using the particle gun delivery system, no transgenic plants of any *Eucalyptus* species have been reported using the biolistic strategy.

2.2.3 *Eucalyptus* transformation using *A. tumefaciens*

Mullins *et al.* (1997) obtained stable transformation of one clone of *E. camaldulensis* using leaf explants inoculated with *A. tumefaciens*. In this

work, the reporter gene β -glucuronidase and the *NPTII* gene were used for selecting transgenic tissues. Ho *et al.* (1998) reported an efficient system for transformation of seedling material from *E. camaldulensis* by the inoculation of hypocotyls segments with *A. tumefaciens*. The work used the Ti-plasmid vector harboring chimeric neomycin phosphotransferase and β -glucuronidase genes.

Moralejo *et al.* (1998) regenerated transgenic *E. globulus* plants using hypocotyls and cotyledons from young seedlings. The explants were inoculated with *A. tumefaciens* and the genes introduced were *GUS* and *NPTII*. Due to confidentiality problems, no precise transformation protocol has been published for most of the eucalypt species. Maunders *et al.* (1997), even though the protocol is not described, reported a reliable transformation system for several species of *Eucalyptus* including commercially important *E. grandis* and *E. globulus*, starting from either mature elite clones or improved seed material.

Transformation of forest tree species remains difficult, particularly within the genus *Eucalyptus*. Harcourt *et al.* (2000) produced transgenic plants of *E. camaldulensis* containing both the insecticidal *cryA3* gene and the *bar* gene by *A. tumefaciens*-mediated transformation of seedling explants. The transgenic lines exhibited tolerance to the broad-spectrum herbicide and resistance to the first instars of chrysomelid beetles. These plants are likely to provide better insect and weed control options in plantations, particularly during the vulnerable establishment phase, mainly in elite genetic background.

Chen *et al.* (2001) regenerated transgenic *E. camaldulensis* plants of elite clones. The genes introduced were cinnamate 4-hydroxylase (*C4H*) and *NPTII*. The main objective of this work was to alter the lignin content of the wood. The transgenic plants were obtained but the wood modification was not evaluated. For *Eucalyptus* species, transformation and plantlet regeneration are generally more efficient with juvenile materials, such as hypocotyls, cotyledons, and leaf disks from *in vitro*-germinated seedlings, than with clonally derived material from field-grown trees that have poor regenerability in tissue culture (MacRae and van Staden, 1999). For forest tree species, the true value of genetic engineering lies in its integration into conventional breeding programs to improve economically important traits that

cannot be modified by conventional means within a reasonable time frame. González *et al.* (2002) obtained transgenic *E. grandis* \times *E. urophylla* plants using seedling material and *A. tumefaciens*. The chimeric construct contained the *nptII* gene and the *Lhcb1*2* gene, coding the 28 kDa chlorophyll *a/b* binding pea protein from LHCII antenna. The transformation system used the inoculation of seeds with *A. tumefaciens* followed by sonication for a few seconds. The objective of the work was to develop a transformation protocol and evaluate the alteration in the process of photosynthesis.

Tournier *et al.* (2003) regenerated *E. grandis* \times *E. urophylla* juvenile clones with the antisense *CAD* gene and *NPTII* like selective gene. The transgene expression was demonstrated with high inhibition of endogenous *CAD* gene, but physiological and biochemical wood modifications were not evaluated.

Valerio *et al.* (2003) developed a procedure for *A. tumefaciens*-mediated genetic transformation of a juvenile *E. camaldulensis* clone using antisense *CAD* gene. Some transgenic lines exhibited a strong inhibition of *CAD* activity, associated with a decrease in transcription. The wood chemical analysis showed no differences in lignin quantity, composition or pulp yield, compared to control trees. These results underline the problems of extrapolating genetic engineering results from a model to a genetically distant target plant species. Other techniques such as RNA interference-type procedures may be used for more complete gene suppression.

Recent developments in transgenic trees can have multidirectional benefits. The benefits range from manipulating generation time, plant protection, wood quality, production of compounds of pharmaceutical value, and recovery of polluted soils.

These successes have opened up avenues to include agronomically more useful genes for transfer into tree species as has been demonstrated in crop plants (Giri and Vijaya, 2000). Following the global trend in forestry biotechnology there are now 24 genetically modified tree species that have been approved for field trials. Recently, it has been emphasized that genetically modified trees can be excellent tools for physiological research (Herschbach and Kopriva, 2002). The research completed so far demonstrates the potential of

these techniques in the improvement of forest tree species. One of the most important aspects of transgenic trees is integration of the introduced gene into the genome and its expression. For long-lived tree species, new questions arise regarding the stability of the integration and expression of foreign genes. Biosafety considerations, including the impact of transgene dispersion through pollen and unexpected effects on nontargeted organisms, are now receiving attention. With recent research developments, molecular genetics provide tools that may allow genetic improvement to make up lost ground. If current progress in tissue culture and genetic transformation combined with biotechnological applications continues, the future may witness super tree species tailored for special agronomic and economic characteristics (Giri *et al.*, 2004).

Private companies claim to possess routine transformation protocols for different Eucalyptus species and hybrids; however, because of the confidentiality issues, these methods are not widely available (MacRae and van Staden, 1999).

3. IMPORTANT AREAS FOR IMPROVEMENT USING GENETIC TRANSFORMATION

3.1 Eucalyptus Diseases, Control Strategies, and Genomic Approaches to Identify Genetic Resistance

3.1.1 Eucalyptus diseases and control strategies

Eucalyptus cultivation in Brazil was limited only to a few thousand hectares until the 1970s, when eucalypts were considered to be practically immune to diseases. The increasing demand for forest products and the need to conserve the native forests pushed the expansion of Eucalyptus plantations to about 3.4 million hectares. About 1 million hectares of this are planted with 362 different clones, of both pure species and hybrids, distributed in areas varying from 10 to 34 000 ha/clone. It is expected that within this year an additional 250 000 ha of eucalypt forests comprising 55 clones will be planted, occupying areas varying from 10 to 9000 ha/clone/company. The expansion of plantations to warmer and

more humid regions conducive to infection by plant pathogens, the regional peculiarities of climate and soil, combined with the possible introduction of diseases from other countries and adaptation of some local pathogens from native Myrtaceae to Eucalyptus species have resulted in the incidence of various fungal and bacterial diseases that cause significant losses in some highly susceptible clones. In spite of the risks, cloning has proved to be an excellent tool for disease control. The knowledge of Eucalyptus species and their interactions with different potential diseases is important to establish strategies to ensure stability of wood production. This review summarizes the main Eucalyptus field diseases and their control.

3.1.1.1 Rust

The symptoms are the appearance of yellow-colored powdery urediniosporic sporulation over the affected organs is the typical feature for rust diagnosis (Figures 4a–c). In highly susceptible materials, the infection causes deformation, necrosis, hypertrophy, mini-cankers, and death of the apical meristems (Figure 4d). Although the uredinal phase is more common and is the main form of pathogen dispersal, less frequently, teliospores can be produced, during the warmer periods, on fully expanded leaves.

Causal agent: *Puccinia psidii* Winter.

Control: The existence of high inter- and intraspecific genetic variability for resistance to rust allows for disease control by planting resistant clones, progenies, or species. *Corymbia citriodora*, *C. torelliana*, *E. camaldulensis*, *E. microcorys*, *E. pellita*, *E. pilularis*, *E. propinqua*, *E. resinifera*, *E. robusta*, *E. saligna*, *E. tereticornis*, and *E. urophylla* are important sources of resistance. In regions, favorable to rust infection, planting of *E. grandis* seeds (provenances: South Africa and Coff's Harbour 9583), *E. phaeotricha*, *E. cloeziana*, *E. globulus*, and *E. nitens* should be avoided. There is, however, ample intraspecific variability, which permits selection and cloning of resistant genotypes for planting. In *E. grandis*, resistance might be dominant and controlled by a major gene (*Ppr-1*) (Junghans *et al.*, 2003). Thus, rust can be controlled through use of resistant progenies, whose seeds are harvested from resistant homozygous mother plants, as practiced by some Brazilian forest industries in São Paulo and

Figure 4 Eucalyptus rust (*Puccinia psidii*). (a) Infected apical shoots of *Eucalyptus urophylla*; (b) pathogen esporulation on *E. globulus* leaf; (c) rust incidence on stem and leaves of *Syzygium jambos*; and (d) necrosis and death of apical shoots of *E. grandis*

southern Bahia. It is also possible to select trees with rapid growth characteristics, which rapidly escape the disease by virtue of the microclimate in the upper canopy being unfavorable for disease development. Similarly, selection can be made from clones of *E. globulus* and related species that rapidly pass through the susceptible juvenile leaf stage to produce resistant adult leaves. In the case of highly susceptible genetic materials of high commercial value, the disease can be controlled by systemic fungicide spray such as triadimenol (Bayfidan 25 PM ou 25 CE) (0.5 g.i.a.l^{-1}) and azoxystrobin (Amistar 500 WG) (0.1 g.i.a.l^{-1}) at 2 weeks intervals. In nurseries, especially in clonal hedges and mini hedges, the disease is controlled by fortnightly spraying of triadimenol or azoxystrobin, using the above concentrations.

3.1.1.2 Cylindrocladium leaf blight

The lesions can develop at the base, at the apex, or at the leaf margins, and can cover a large portion of the leaf area, inducing severe premature defoliation of the lower, middle, and apical thirds of the tree canopy during the 1st and 2nd years after planting (Figure 5a). It is believed that, when only the basal or middle third of the canopy is affected, the trees tend to recover. However, under disease favorable conditions, the apical portion is also defoliated, especially in highly susceptible materials, leading to reduced plant growth. Defoliation also allows for high light intensity penetration into the stand leading to growth of competing weeds (Figure 5a). Disease symptoms can vary depending upon the species of *Cylindrocladium* and *Eucalyptus*. The

Figure 5 *Cylindrocladium* leaf blight. (a) Defoliation in commercial plantation of eucalyptus hybrid (*E. grandis* × *E. urophylla*), the arrows indicate growth of weeds due to light penetration increase; (b) smaller leaf spot, typical of *C. pteridis*; and (c) larger leaf spot, typical of *Cylindrocladium* spp.

leaf spots of *C. pteridis* are smaller, circular, or elongated and light gray progressing to light brown in color (Ferreira *et al.*, 1995) (Figure 5b), while those of *C. candelabrum*, *C. floridanum*, *C. ilicicola*, *C. parasiticum*, and *C. scoparium* are larger, light to dark brown with a gray green halo (Alfenas *et al.*, 2004) (Figure 5c). In most *Eucalyptus* species, the

lesions are light or pale brown, but in *E. cloeziana* they are dark brown.

Causal agents: *C. candelabrum*, *C. floridanum*, *C. ilicicola*, *C. ovatum*, *C. parasiticum*, *C. pteridis*, and *C. scoparium*.

Control: Considering the natural recovery of infected plants during subsequent periods,

climatically unfavorable to the disease, no control measure is currently used. However, because of high reduction of the photosynthetic area, a significant loss in volume is expected, which may justify adoption of control measures to reduce potential losses. In this case, planting blight-resistant progenies, provenances, species, and clones is the best control strategy. The determination of inheritance model and genetic base is essential for a breeding program to obtain resistant materials.

3.1.1.3 *Rhizoctonia leaf blight*

In field plantations and clonal hedges, the infection starts on the leaves of the lower branches and progresses to the plant apex, causing intense leaf blight and defoliation (Silveira *et al.*, 2000) (Figure 6a). The disease is characterized by large and irregular leaf spots (Figures 6b and c). Depending on the disease intensity, whitish-mycelium-covered branches and leaves can be observed (Figure 6b), with the possible presence of whitish or light to dark-brown sclerotia (Figure 6d). Initially, the affected leaves show irregular light-gray to light-brown lesions of different sizes leading to blight of almost all leaves that become pale in color. Initially, infected leaves remain attached to the plant, but tend to fall with time. Other marked characteristics of the disease are hanging leaves attached by the fungal hyphae, adhering to one another, and connected by hyphae resembling a web (web-blight) (Figure 6c). The pathogen survives in soil, from which it disseminates by water splash to the surface of lower leaves or by growing epiphytically up the trunk reaching the higher portions of the canopy. In general, the fungus does not sporulate, and the most important features are sclerotia formation along the infected organs, right angle branching of hyphae, and presence of a constriction at the first septum in the branched hyphae when observed under the microscope. The sexual phase of some isolates of *Rhizoctonia solani* (*Thanatephorus cucumeris*) can be produced under controlled conditions, but is rarely found in natural infections (Silveira *et al.*, 2000).

Causal agents: *Rhizoctonia solani* (AG1-1B) and binucleate species of *Rhizoctonia* not yet identified.

Control: Although there are no studies about the genetic variability for resistance, it is unlikely that

resistant genotypes will be found within eucalypt species. However, artificial inoculations should be conducted to examine this hypothesis.

3.1.1.4 *Bacterial leaf blight*

At the initial phases of infection, the disease is characterized by water-soaked translucent leaf spots (Figure 7a), resulting from water leakage into the intercellular spaces, and is followed by intense defoliation, girdling, and mortality of the apical portion of highly susceptible materials (Figure 7b). As the disease progresses, the lesions become necrotic and dry with perforations and deformation of the leaf blade (Figure 7c). Its precise diagnosis requires laboratory examination, using exudation tests in which bacterial slime emanates from newly formed lesions.

Causal agents: Species of *Xanthomonas axonopodis*, *X. campestris*, *Pseudomonas cichorii*, and others (Gonçalves, 2003).

Control: Selection and planting of resistant genotypes.

3.1.1.5 *Phaeophleospora leaf blight*

Angular purple brown spots, distributed on both sides of mature leaves (Figures 8a–c), result from exudation of conidial masses (cirri) (Figure 8d), black sporulation resembling black mold. The disease is sometimes confused with the leaf spots caused by *Cylindrocladium*, plant bacterial infection or phosphorus deficiency, especially if observed on the upper leaf surface. However, typical sporulation of the pathogen is the major characteristic for diagnosing the disease. It generally occurs on old leaves of plants in the field or in the nursery.

Causal agent: *Kirramyces epicoccoides* (*Phaeoseptoria epicoccoides* = *Phaeophleospora eucalypti*), teleomorph *Mycosphaerella suttoniae* (Crous, 1998).

Control: No specific control measure has been used, but selection and planting of resistant genotypes may be effective.

3.1.1.6 *Pilidiella leaf spot*

Large, light brown to pale leaf spots, with dark concentric halos (Figure 9) formed by the

Figure 6 *Rhizoctonia* leaf blight. (a) High defoliation; (b) leaves with lesions and pathogen mycelium (arrows); (c) leaves with blight symptoms stuck each other, with the fungal mycelia holding the dead leaf; and (d) dark-brown sclerotia over infected leaves

Figure 7 Bacterial leaf blight. (a) Water-soaked translucent leaf spot on *Eucalyptus cloeziana* plants; (b) death of apical portion of *E. urophylla*; and (c) differences in the symptoms

exudation of spore mass. Typical conidiophores and conidia of the pathogen can be observed by microscopic examination of histological sections through the pycnidium. This fungus penetrates host tissues through wounds (leaf friction by the strong winds), insect (thrips, larval, and

aphids), or mite injuries and also through the lesions caused by other leaf pathogens as *P. psidii* and *Cylindrocladium* spp. The photosynthetic area is reduced in case of high disease severity, but defoliation is not usually observed.

Figure 8 *Phaeophleospora* leaf spot. (a) Angular purple brown spot with fungi sporulation; (b) healthy leaf and leaves with symptoms; (c) detail of angular spots; and (d) exudation of conidial masses (cirri)

Causal agent: *Pilidiella eucaliptorum* (= *Coniella fragariae*).

Control: No specific control measures are employed, but planting of resistant clones is the best strategy of control.

3.1.1.7 *Aulographina* leaf spot

Circular or elongated dark-brown corky spots occur over the main vein, petiole, and twigs (Ferreira, 1989) (Figures 10a and b). Superficial dark-brown to black, elongated, curved, or branched fruiting bodies with a longitudinal slit (hysterothecia) are formed over the lesions (Ferreira, 1989) (Figure 10c). Asci and the ascospores of the fungus can be observed by microscopic examination of histological sections of the ascomata.

Causal agent: *Aulographina eucalypti*.

Control: The disease does not cause important damage, therefore, no specific control measures are being used.

3.1.1.8 *Mycosphaerella* leaf spot

The fungus infects young leaves of *E. globulus*, *E. nitens*, and *E. dunnii* and mature leaves of many other species, including *E. grandis*, *E. saligna*, *E. urophylla*, and their hybrids. The spots vary from circular to irregular circular shape and are light to pale brown, being darker on the lower leaf surface (Figures 11a–d). Dark ascomata, asci, and ascospores are formed on the lesions.

Causal agents: The disease is caused by various species of *Mycosphaerella*. Although it is not well known, it is believed that *M. parkii* (anamorph = *Stenella parkii*), *M. suberosa* (anamorph = not determined), and *M. suttoniae* (anamorph = *Phaeophleospora epicoccoides*) are the most common species on Eucalyptus in Brazil.

Control: No control measures have been adopted in Brazil, but for species such as *E. globulus*, *E. maidenii*, *E. dunnii*, and *E. nitens* it is possible to select faster growing clones, which rapidly pass to the less susceptible adult stage and, thus escape the disease.

Figure 9 *Pilidiella* leaf spot. Leaf spot showing pathogen penetration by wounds or other pathogens lesions

3.1.1.9 *Cryptosporiopsis* leaf spot

The pathogen infects leaves on the basal third branches without causing significant defoliation. The lesions are light to grayish-brown of varying sizes, semicircular or circular in shape (Figure 12a). They are encircled by a dark halo and the center has a dark rust colored spot of up to 6 mm diameter (Ferreira *et al.*, 1998) (Figure 12b). Typical conidiophores and conidia can be observed microscopically in the histological sections of conidiomata. Like *Pilidiella eucalyptorum* and *Hainesia lythri*, the fungus penetrates the host through wounds.

Causal agent: *Cryptosporiopsis eucalypti*.

Control: Since the disease does not cause significant economical losses, no specific control measures have been adopted. However, it is believed that planting of resistant genotypes may be the best strategy.

3.1.1.10 *Ralstonia* wilt

The first symptoms appear on 4- to 8-month-old plants. Initially, the leaves show wilting, becoming reddish, yellowish (Figure 13a), and latter pale to dark-brown in recently dead plants (Figure 13b). Stem section of wilted plants, exudates bacterial pus as cream-colored drops (Figures 13c and d).

Figure 12 *Cryptosporiopsis* leaf spot. (a) Lesions on the lower (left) and upper side (right) of leaf and (b) detail of spot lesions

Causal agent: *Ralstonia solanacearum* (= *Pseudomonas solanacearum*).

Control: Production of plantlets exempt of contamination with the pathogen.

3.1.1.11 *Ceratocystis* wilt, dieback, and canker

Initially are observed epicormic shoots along the trunk, and depression in the bark, then dieback, canker, wood discoloration, and wilt, leading to plant death (Figures 14a–d, Figures 15e–g).

Causal agents: *Ceratocystis fimbriata*.

Control: Planting of resistant genotypes.

3.1.1.12 *Eucalyptus* canker

Infection may be observed on 6-month-old plants (Figure 16a). When it occurs on young or adult plants of small stem diameter or on mini-stumps in clonal hedges, usually causes death by stem girdling. The canker can occur at any height of the stem, but usually occurs at the tree base (basal canker), causing superficial or deep lesions on the bark surrounded by callus (Figures 16b–d). A typical canker is formed if the lesion is deep and localized at a specific point of the trunk, while in superficial lesions, not reaching the cambium, the plant responds by producing new tissues resulting in the trunk swelling and bark cracking at the

Figure 13 *Ralstonia* wilt. (a) Plant with wilt symptoms and basal defoliation; (b) dead plants; (c) symptoms in the stem section immediately after cut; and (d) exudates bacterial pus (arrows)

infection point (Figure 16e). The weakened trunk at this point can break (Figure 16f), especially in regions of strong winds. Dark pycnidia and or perithecia produced on dead bark are the signs of the disease, essential for unequivocal diagnosis.

Causal agent: *Chrysophorte cubensis* (= *Cryphonectria cubensis* = *Diaporthe cubensis* = *Endothia eugeniae*).

Control: Planting of resistant species, provenances, families, or clones. *C. citriodora*,

Figure 14 Dieback, canker, and wilt caused by *Ceratocystis fimbriata*. (a) Development of basal shoots due to veins colonization by the fungus; (b) natural infection showing dieback; (c) dead plant; and (d) canker

Figure 15 Continue from Figure 14. Transversal (e) and radial (f) xylem discoloration symptoms; and (g) inoculated plant with wilt symptoms (left), and detail of stem discoloration (right)

C. torelliana, *E. cloeziana*, *E. pilularis*, *E. paniculata*, *E. pellita*, *E. urophylla*, *E. robusta*, *E. resinifera*, and *E. microcorys* are the more resistant species, while provenances of *E. grandis* and *E. saligna* are the most susceptible. However, there is a high intraspecific variability as to

resistance, which allows for selection and cloning of resistant genotypes for planting. In clonal hedges, canker can be controlled by selective shoot harvesting that reduces the stress on the mini-stumps, avoiding predisposition to the disease.

Figure 16 Eucalyptus canker caused by *Chrysophorte cubensis*. (a) Scattered death of *Eucalyptus saligna* plants in the field; (b) typical canker without bark removal; (c) typical canker (deep lesion flanked by callus); (d) basal canker; (e) trunk swelling, and bark cracking on the infection point; and (f) plant with canker, broken by wind at the infection point

3.1.1.13 Pink disease or rubellosis

Lesions and girdling are observed on the stem and branches of 1- to 3-year-old plants. A pink colored mycelium grows on young lesions (Figures 17a and b). Epicormic shoots emerge from below the girdled portion of the stem (Figure 17a). Later, the lesions dry out and lose the typical color (Figure 17c), leaving behind cankers (Figure 17d) on the thicker nongirdled stem and branches. The stem may break and lose apical dominance (Figures 17e and f). Pink to salmon colored mycelium, containing basidia and basidiospores may be observed on the lesions.

Causal agent: *Erythricium salmonicolor* (= *Corticium salmonicolor*).

Control: Selection and cloning of resistant genotypes.

3.1.1.14 Coniothyrium canker

Small discrete necrotic lesions with a strong depression in the bark are formed along the trunk (Figures 18a–c). The infection occurs through the younger tissues of the green stem. In highly susceptible genotypes, the lesions coalesce and cause extensive necrosis, generally followed by kinopocket formation (gummosis) (Figure 18d) and reduced plant growth, dieback, and emission of epicormic shoots along the trunk, due to partial cambium death and stem girdling. The fungus

Figure 17 Pink disease or *Eucalyptus rubellosis*, caused by *Erythricium salmonicolor*. (a) Pink mycelium and epicormic shoots below infected area; (b) and (c) stem lesion showing mycelium growth and bark cracking; (d) typical canker; (e) trunk breaks on the infection point; and (f) trunk break and loss of apical dominance

produces globose and substomatal pycnidia, containing conidiospores and conidia.

Causal agent: The disease, first described in South Africa, was attributed to *Coniothyrium zuluense* (Wingfield *et al.*, 1997). In Brazil, the disease was found on *E. grandis* and attributed to *Coniothyrium* sp. (Ferreira, 1977).

Control: In Brazil, it has not caused serious damage to the affected plants, thus no control measures have been adopted.

3.1.1.15 Botryosphaeria canker

The infection occurs in young tissues, resulting in breakage with the forking of the main stem at the infection point, gum exudation, darkening, depression, and bark cracking (Figures 19a–f). Generally, the lesions are superficial and confined

to the bark region, showing fructification of the pathogen. Pseudothecia containing asci and ascospores are formed on the lesions.

Causal agent: *Botryosphaeria ribis*.

Control: No specific control measures have been adopted.

3.1.2 Approaches to identify genetic resistance

3.1.2.1 Sources of disease resistance and breeding strategies

Considering that a relatively small number of clones, possibly with narrow genetic base, are planted in some regions of Brazil, it is imperative to establish an interspecies breeding program to obtain new resistant genotypes. Predicting the

Figure 18 *Coniothyrium* canker. (a), (b), and (c) Necrotic lesions with a depression in the bark; and (d) details of the xylem infection with kinopocket formation

Figure 19 *Botryosphaeria* canker. (a) Canker; (b) depression and bark cracking; (c) gum exudation; (d) break of apical trunk; (e) forking of main stem in the infection point; and (f) details of superficial infection in the bark region

eventual dry periods and predominance of high temperatures, drought resistant species, such as *E. camaldulensis*, should be considered for crossings. Other species, such as *E. pellita* (Papua New Guinea provenance) and *E. urophylla*, are excellent source of resistance to canker. The former is also an important source of resistance to leaf blights. On the other hand, *E. globulus* can be used as a gene source for reducing the lignin

and extractive contents, increasing wood density, improving pulp yield, and fiber quality, while *E. grandis* (Atherton or Coff's Harbour) has high adaptability and is suitable for high cellulose yield. Introgression of genes of *E. globulus* should be carried out using pollen obtained from elite mother plants from the southern part of Brazil, Uruguay, Spain, Chile, Portugal, or Australia, where it is possible to cultivate these plants as a pure

species. In the final composition, hybrids should contain 50–75% genes of *E. grandis*, obtained by a series of crossing and back crossings, and selfings if necessary. However, *E. deglupta*, *E. resinifera*, and *E. robusta* can also be tested, although little is known about their resistance to diseases, fiber quality, and adaptability. Since *E. globulus* and *E. pellita* have contrasting characteristics, for example, disease resistance, site adaptability and extractives, and lignin content, they should contribute a maximum of 12.5% of genes in constituting interspecific hybrids. Since wood lignin and extractives have essential functions in defense mechanisms, reduction of their concentrations can potentially result in higher susceptibility. Thus, in each generation of crosses, the resistant genotypes should be selected through artificial inoculation with specific pathogens of interest for each region. It is also essential to determine the resistance of commercial clones and its genetic basis to different diseases such as stem canker, rust, leaf blights (fungal and bacterial), ceratocystis wilt, and bacterial wilt through artificial inoculations of controlled crossing progenies. When resistance is dominant, resistant homozygous mother plants should be used for seed harvesting, since irrespective of the pollen origin, the progeny should be resistant.

3.1.2.2 Genomic approaches to identify genes for rust resistance

Currently, one of the biggest threats to Eucalyptus plantations is neotropical rust caused by the biotrophic fungus *P. psidii*. This disease attacks young trees, normally younger than 2 years old, thus it principally affects nurseries and recently planted areas, and depending on the severity of the infestation can result in a significant to almost total loss of production. In order to investigate the genes differentially expressed during *P. psidii* infection, Moon *et al.* (2007) constructed two SAGE (serial analysis of gene expression, Velculescu *et al.*, 1995) libraries representing susceptible and resistant material. Susceptible and resistant individuals were selected from a segregating population of half-siblings of *E. grandis* (Suzano Papel e Celulose), after being naturally infected with *P. psidii* Winter under field conditions. Bulks representing each phenotype

Table 4 The percentage of transcripts for the identified genes within each functional category^(a)

Category	Susceptible library (%)	Resistant library (%)
Metabolism and energy	4.4	20.1
Processes	32.3	31.4
Transport	1.1	2.3
Structural and organization of structure	4.8	16.5
Information pathways	19.3	1.7
Unknown function	38.1	28.0

^(a)Reproduce from Rison *et al.* (2000). © Springer

were formed using ten susceptible and ten resistant individuals selected from an *E. grandis* segregating population of half-siblings (Suzano Papel e Celulose). 31 645 and 39 964 tags, representing a cumulative gene count of 4095 and 5213, were generated from the susceptible and resistant bulks, respectively. The Z-test indicated that 239 were preferentially expressed in the susceptible library and 232 in the resistant. Using the National Center for Biotechnology Information (NCBI) public database (<http://www.ncbi.nlm.nih.gov>), which contains approximately 15 000 Eucalyptus ESTs and complementary DNAs (cDNAs), the authors were able to associate nucleotide sequences to 40 and 72 tags, susceptible and resistant, respectively.

Table 4 shows the differences in the number of transcripts within each functional category for the differentially expressed genes for the susceptible and resistant libraries. It can be seen that in the susceptible library the expression of genes involved in metabolism and the production of energy is considerably reduced showing about 25% of the level observed in the resistant material, probably reflecting the generally debilitated state of the infected susceptible plants. Genes preferentially expressed in the resistant library in this category were associated with the metabolism of sugar nucleotides and carbohydrates, indicating a higher biosynthetic activity directed toward the production of structural components.

Another interesting category was structural and organization of structure, which represents the genes involved in cell wall synthesis and cytoskeletal organization. This category was reduced in the susceptible material, approximately 33% of the level observed in the resistant library. Genes involved in the synthesis of the cell wall were

preferentially expressed in the resistant library, including those associated with cellulose and lignin biosynthesis. We also observed genes involved in the formation of the cytoskeleton, the tubulins, preferentially expressed in the resistant material.

Although the number of transcripts produced for the processes category was almost the same in the two libraries, the genes that they represent show differing pictures in the presence of the pathogen. In the susceptible library, the preferentially expressed genes demonstrated a response to oxidative stress and general stress response proteins. However, the resistant material showed the induction of genes more specifically for defense responses, including a catalase and a kinase.

The category representing the information pathways was almost ten times more expressed in the susceptible than the resistant material. These genes were associated with ubiquitin regulated protein turnover and proteases were mainly expressed in the susceptible library indicating a very active protein degradation system.

From these preliminary results Moon *et al.* (2007) suggest that two completely different processes are occurring in the susceptible and resistant plants. Firstly, from the generalized lesions observed in the susceptible material, it is obvious that plant is fighting a losing battle against the pathogen and is trying to limit the oxidative damage within the infected leaves and active proteolysis is occurring within the areas surrounding the necrotic lesions. Secondly, in the resistant plants various distinct processes are occurring simultaneously contributing to the expression of the resistant phenotype. Primary metabolism shows an increase in the expression of genes involved in the production of the raw materials for cell wall formation, sugar nucleotides, and carbohydrates. Coupled to this is the preferential expression of the genes associated with cellulose biosynthesis and the principal genes involved in lignin biosynthesis and polymerization, most probably re-enforcing the cell wall structure making fungal penetration more difficult. The preferential expression of genes involved in the formation of the cytoskeleton and vesicular transport factors would also indicate that the process of cellular polarization is occurring (reviewed by Schmelzer, 2002). Cellular polarization is defined as the process of cytoskeletal organization that allows the translocation of the cell nucleus

and transport of vesicles containing cell wall matrix material or specific defense related proteins directly to the site of infection. This process is documented as being an important process during the host cell response to pathogens. The authors also observed catalase and a kinase, preferentially expressed in the resistant material, probably involved in signal transduction during the initial infection and later in the process of systemic acquired resistance. Unfortunately, they were unable to identify any gene specifically involved in the destruction of the fungal pathogen, such as chitinases, thaumatin, or R genes, probably due to the lack of publicly available Eucalyptus ESTs that represent these genes. The authors suggest that sustainable resistance to *P. psidii* in *E. grandis* is the result of more than one predominant gene.

3.2 Wood Quality and the Transcriptome Involved in Eucalyptus Wood Formation

3.2.1 Wood quality requirements for pulp and paper, charcoal biomass fuel end-uses

Eucalyptus wood has gained a respectable position as raw material for several utilizations. Thanks to an excellent forestry technology, which was developed in countries like Brazil, Portugal, South Africa, Spain, Chile, Uruguay, and Australia, Eucalyptus has reached the status of “super-tree”. In a historical first moment, the efforts coming from tree breeding and silvicultural techniques were directed to the production of volume and/or weight in the trees. The acquired productivity would provide the desired competitiveness to the wood-based businesses. Wood-specific unit costs and forest operation costs were dramatically reduced by these technologies. Thanks to the high productivity of the planted forests and to the low production costs, Eucalyptus wood soon gained importance with several industries, such as pulp and paper, charcoal for steel manufacturing, lumber, and furniture. This raw material could easily supply fibers and biomass fuel, in unbeatable conditions. In a short period of time, the world quickly became surprised and enchanted with Eucalyptus for its fast growth rates and wood quality. The quality targets are becoming more and more sophisticated for each of the wood

utilizations. In the beginning, the selection of the raw materials was based on productivity (volume or dry weight), yields in the manufacturing conversion processes, and low wood costs. Today, the needs for product differentiation and for adding value in the production chain have oriented wood and trees to new requirements. Besides the traditional needs for productivity, yields, and costs, there are two new and important wood requirements: tree and wood uniformities. The control of forest variability may be seen as a simple task, but it is tremendously difficult. The anticipation using the cloning techniques was very high with the aim of controlling variability. However, the dream of having very similar trees has not been realized. Although a lot more uniform, the cloned trees show a considerable level of variability. This happens in the tree characteristics and in the wood quality (anatomical, physical, and chemical properties).

Currently, the foresters have placed attention on the production of trees having good shape, straight trunks, higher shape factors, and low percentage of bark. Additionally, the foresters also consider the resistance of the trees to pests and diseases, and tolerance to detrimental weather conditions (frost, winds, water deficits in the soil, flooding, etc). All these issues are demanding a lot of attention and research. The target for high quality *Eucalyptus* planted forests is not that simple. Even being healthy, with good shape and fast growth, the trees may not be suitable to some end-uses. For example, *E. grandis* trees, with fantastic growth rates, and tree shapes, may not be well suitable to the production of charcoal. The wood density may be too low for this purpose, the logs become very cracked when dried and the charcoal is poor in density, in calorific value per volume, very bulky, and generates more fines during manufacturing and handling. On the other hand, trees of *Eucalyptus robusta* may give low pulp yield in the conversion to kraft pulp due to the excess of extractives and/or lignin.

In short, now it is just the right time not only to have forests and trees, but also with end-use oriented qualities. A very good forest oriented for the production of charcoal will not be so desirable for kraft pulping, since both utilizations have opposite requirements in terms of wood lignin content. Whereas for charcoal, the best wood quality is the one with very high lignin content

and wood density but for kraft pulping, lower the lignin content the better. The wood density for pulping cannot be very high due to the problems with liquor impregnation.

Although the knowledge for the required wood characteristics is well understood by most researchers, the truth is that we are still finding many mistakes in the way breeding programs are being performed. The major mistake is the precarious sampling procedure being used in the majority of the tree and wood quality improvement programs. As far as the variability remains high for many qualitative parameters, even for cloned forests, the size of sampling should be larger than is generally used. Additionally, the sampling should be more representative, collecting samples from all segments of the population according to their frequency. Currently, there is a trend to take few trees with the average volume. Average sized trees are not synonymous of trees with average basic density, or average lignin content, etc. The first recommendation has to be made related to trees and wood sampling. Definitively, the size and the representativeness of these samples need to be improved. The second recommendation is to increase the number of analyses, the number of replications for each required quality parameters being evaluated. In general, the analyses are made with a single measurement and the mean value is used in the tree and wood improvement program. Depending on the statistical error that the forest breeder is willing to allow, the numbers of replications have to be considerably higher. There is a chance that the breeder is accepting what is accepted as a good genome but is definitively not good for a given property of the tree or wood. This is something that needs to be immediately reevaluated.

3.2.1.1 *Eucalyptus* wood quality requirements for the production of kraft pulp

Independent of the pulp mill, the pulp sector has fundamental issues including high productivity, high operational efficiency (no losses, no problems, no breaks, and no stops), low production costs, and uniform quality of the process and products. For achieving these targets, the raw material must be as uniform as possible so as not to cause

strong impacts on the pulping process and pulp qualities. To reduce this variability, the pulp mill engineers blend woods. Blending very different wood is acceptable if the result has a reasonable average quality. This is not an ideal situation, but it is the most usual.

When the pulp maker asks for uniform wood he is not only referring to wood basic density, but also to a series of wood quality parameters that are very important in the conversion process: proportion of bark in the wood chips, wood chip dimensions, decay level of the wood, wood moisture, wood chip bulk density, etc. The objective is to have a cooking and bleaching operation with the minimum variability, without undesirable surprises. The final quality must be uniform and within the specification limits and the process losses should be minimal. When the mill manager standardizes the wood intake, the first thing is to guarantee an appropriate quantity of dry wood being fed to the digesters. It is important to keep chip bulk density as uniform as possible for continuous addition of the same dry weight of wood to the digesters. The mill manager is carrying out "the management of the quantity of dry wood taken into the mill." When a uniform flow of wood dry weight is guaranteed, the liquor, steam, and chemical flows do not sharply change and the process runs smoothly, and the process and product quality is more easily achieved.

The second type of management is "management of wood variability" that tries to guarantee a low variability of wood parameter such as wood basic density, lignin content, extractives content, and active alkali consumption during kraft cooking, bleaching chemical consumption, yields in the conversion of the wood to bleached pulp, etc. There are other associated goals, such as to minimize the overload of dry solids to the recovery boiler turnover; reduce the specific wood consumption in cubic meters of wood by air-drying metric tons of pulp; guarantee stable quality and to reduce the production costs.

Management of dry quantities and management of wood variability are the basic requirements in any pulp mill. Having fulfilled these needs, the next type of management is "management for product differentiation" or "tailor-made orientation in the manufacture of products." This type of management requires substantial changes and offers important challenges to the mill personnel.

The changes may happen in wood quality (for example, low and high basic density woods), process conditions (for example, ECF or ECF-Light bleaching sequences), or even other recently added qualities (certified or noncertified wood). Differentiation of products is more easily achieved in mills with more than one fiberline. This means that the mill may run each fiberline with a differentiated product, without experiencing the usual troubles in making the transition from one product to another using a single fiberline. Anyhow, the tailor-made concept will only be a winner when the pulp maker has guaranteed the two previous types of management: dry quantity and variability. It is very simple to say, but very difficult to understand and to implement. Conflicts and misunderstandings are frequent between commercial, production, and product innovation areas in a pulp mill. Each of these areas has their own needs, product uniformity, product uniqueness, and product differentiation. As a result, few Eucalyptus pulp mills have products that may be said to be completely differentiated in their products portfolio. Most of the pulp manufacturers aim to have a single product, as uniform as possible, with the minimum cost, and maximum in productivity and in operational efficiency.

It is relatively difficult to say what is the single most important wood characteristic for a given pulp mill. The reason is that there is not a universal wood property to be managed. Depending on the pulp mill bottleneck, wood quality is defined to guarantee the maximum performance of a particular mill. The most common bottlenecks are the capacities of digester, recovery boiler, drying machine, lime kiln and alkanization, pulp washing, pulp bleaching chemicals. As a conclusion, it may be said that the type of mill bottlenecks will define the most desirable wood quality. This is the case for existing mills. For new greenfield mills, the quality may be previously built at the forest. However, soon the mill starts up, and the bottlenecks will appear to define the new wood quality standards. This is the reality, no doubt about it. This is also the cause of domestic conflicts within the company.

A list of important properties of Eucalyptus wood that influence the kraft pulp production process is presented.

- Wood cleanliness. This is an item not clearly understood by many forest managers, who try to mechanize their operations to reduce costs and do not realize the impact on wood cleanliness, which in turn affects pulp mill efficiency. The wood must be as clean as possible in terms of bark, soil, leaves, stones, decayed wood, etc.
- Wood basic density. To the pulp maker, the uniformity of wood density is very important. The more uniform is the wood, the better and simpler is the management of the quantity and variability. In many mills the design capacity allows the use of light woods, which are easier to be impregnated with cooking liquor and demand a lower alkali charge. However, when the digester is the bottleneck, denser wood is used to raise mill production in the digester. Again, the kind of bottleneck is the source of specifications for the wood quality. When the mill solves the bottleneck using wood quality, normally it is the forest breeders who need to produce wood with the desired specification, sometimes simply by changing clones or searching for new clones that fit the specifications. Pulp mills are short-term oriented and forest breeders are long term. The conclusions and behaviors are very different in both cases. Depending on the bottleneck experienced, some mills prefer to use low-density wood ($0.40\text{--}0.45\text{ g cm}^{-3}$), other medium ($0.50\text{--}0.55\text{ g cm}^{-3}$), and others high density ($0.55\text{--}0.60\text{ g cm}^{-3}$).
- Active alkali consumption and pulp yield. These variables are a consequence of the wood characteristics such as lignin, extractives, ash, density, *Eucalyptus* species, tree age, etc. The pulp maker wants to manufacture more and better, without overloading the production process. For this reason, the wood quality improvement programs need to be oriented by processing qualities in pulp manufacturing.
- Specific wood consumption ($\text{m}^3/\text{adt} = \text{cubic meters of wood by air-dry ton of pulp}$). This consumption is the result of many interconnected wood and kraft process variables: wood basic density, pulp yield, decay of wood, process losses of fibers, wood chipping operations, etc. The specific consumption of the wood is responsible for important fraction of the pulp cost. Wood is the main component in the pulp production cost, even in low-cost wood countries. For this reason, it is one of the most vital indicators to the mill manager. All qualitative wood characteristics that may impact the specific wood consumption should be optimized.
- Lignin content and lignin type. Lignin is abundant in *Eucalyptus* wood, especially those planted in Brazil. The total lignin content in Brazilian *Eucalyptus* wood varies from 24% to 32%, relatively high for hardwoods. This affects the pulp yield in the conversion to kraft pulp, as well as the consumption of active alkali and the generation of dry by the recovery boiler. There are *Eucalyptus* species with lower lignin contents and as such are more appropriate for pulping operations. *E. globulus* and *E. dunnii* when compared to *E. urograndis*, *E. urophylla*, *E. grandis*, and *E. saligna*, offer woods of 2–8% less total lignin (based on dry wood). For this reason, tree breeders are trying to combine in hybrids for cloning these wood characteristics in association with the fast growth rates from other species. Thus, gains in wood-specific consumption, alkali charges, and pulp yield should be significant. As a rule, for 1.2–1.5% reduction in lignin, the kraft pulp yield increases 1% based on dry wood. The active alkali consumption reduces around 0.2–0.3% for the same lignin reduction. Therefore, the production of low lignin clones is a new challenge for hybridization and cloning, without the need for genetic modification to insert genes for low lignin in the wood. At the same time, in Portugal, the need to maintain the purity of *E. globulus* and to improve the forest productivity should be possible through genetics and silviculture. With this in mind, the Portuguese foresters are willing to improve the productivity of *E. globulus* in equivalent tons of pulp per hectare per year. In Brazil, *Eucalyptus* commercial forests produce from 9 to 15 $\text{adt ha}^{-1}\text{ year}^{-1}$, while in Portugal the *E. globulus* forests produce 6–8 $\text{adt ha}^{-1}\text{ year}^{-1}$. Even with lower growth rates, the *E. globulus* trees are offering a competitive raw material thanks to the better wood basic density, lignin content, and pulp yield. However, not only the quantity of lignin in the wood is important, but also its quality. Lignin with high syringyl/guaiacyl ratio offers easy cooking and

pulp bleaching because guaiacyl type lignin is more difficult to be removed during the chemical reactions. This ratio in Brazilian *Eucalyptus* varies from 2 to 3, but in Portuguese *E. globulus* it may vary from 2.5 to 6.

- Extractives content. Extractives are undesirable in the pulping process because they have an impact on pulp yield and contaminate the process and the final product with pitch. The total extractives content in the *Eucalyptus* wood varies as a function of species, age, silvicultural stresses, pests, and diseases, etc. Values are variable from 1.5% to 6%. Extractive can be removed in several ways, normally extracting them with a solvent (water, caustic soda, ethanol, toluene, dichloromethane, etc.). In all cases, the lower the extractives, the better is the pulping, bleaching, and cleanliness of the final product.
- Ash content. Wood is rich in mineral elements and these are absorbed by the trees as nutrients. When the wood is harvested, the minerals are exported from the soil through the trees to the mills. Minerals are measured in the wood as ash content, after burning the sawdust of the sampled wood. Ash content in *Eucalyptus* wood varies from 0.3% to 1.0%, the most important minerals being calcium, potassium, and magnesium. With the trend to use closed water cycles in the pulp mills, these minerals are able to build up in these systems, bringing enormous problems with incrustations, pitch formation, formation of “stones” in the recovery boiler, etc. Ash content is very variable among the *Eucalyptus* species and for this reason it is an important parameter for tree breeding. When low ash woods are selected, the exportation of nutrients from the soil is minimized. The trees are more efficient in wood formation using or immobilizing fewer minerals in their tissues. These minerals, also known as nonprocess elements, leave the pulp mills as pollution (solid residues, air pollution particulate or dust, and dissolved ions in liquid effluents). This means that a fantastic natural resource is transformed into pollution, in mills not oriented to prevent or to develop clean production techniques for controlling and recycling these minerals. For this reason, the emphasis today is to prevent the intake of minerals into the mills, both those in the wood

composition, or as contaminants (soil, stones, etc.). Bark is also very rich in ash (about 5–10 times richer in ash content than wood), thus the contamination of logs and chips with bark brings additional amounts of minerals into the milling process affecting pulp making.

3.2.1.2 *Eucalyptus* wood quality requirements for the production of paper

All these wood characteristics and related consequences mentioned until now favor the pulp mills in their targets for productivity, costs, and efficiency. However, they are only part of the wood features to be evaluated. *Eucalyptus* pulp is a raw material for the manufacture of several grades of papers. For each paper grade and for each paper mill design, there are different wood and pulp quality requirements. It is important to mention that, independent of the type of paper to be manufactured, all the paper makers have what are known as basic physiological needs. These needs are similar to those for the pulp manufacturer: productivity, operational efficiency, quality, and costs.

Productivity requires a high-speed paper machine, fast drainage at the wet end, high consistency after the wet presses, and minimum number of paper sheet breaks along the machine. Quality implies the maximum percentage of paper in the specification range and minimum generation of broken paper lines. Machine operation efficiency is the dream of any paper manufacturer. He wants his machine working smoothly, at the maximum speed as possible, no breaks, and achieving the required quality in the manufactured products. The consequence of all this is that the specific unit cost is also optimized here. No doubt that a good pulp is the one able to provide good paper machine runnability and appropriate quality in the end product.

Some of the desired pulp properties are closely related to these performances and directly related to wood quality, others depend on the conversion of wood to pulp (cooking, bleaching), and many are a combination of these two factors influencing the pulp quality. For example, some properties that are related to pulping and bleaching are viscosity and degradation of cellulose chains, fiber deformations and individual fiber strengths,

surface charges in fibers, etc. One very important pulp property that is related to wood quality and pulp conversion is the hemicellulose content in the pulp. This parameter depends on the wood content and the ability of the pulping process to preserve it in the fibers.

There are many pulp properties that are dependent both on wood quality and on pulping/bleaching processes. There are also many cases where the exigencies are placed a lot on the wood quality, when the wood is not the only factor to determine the pulp quality for paper. Wood quality affects properties such as WRV—water retention value, WWS—wet web strength, fiber bonding, and individual fiber strength. However, other pulp properties are directly related to pulp manipulation processes, for example, the fine content of the pulp (parenchyma cells and fiber fragments) is generated in operations such as wood chipping, pulp pumping, pulp dynamic mixers, pulp dewatering presses, etc.

As a rule, there are some physiological properties that any pulp has to fulfil to be acceptable to papermakers. They are related to the following:

- Drainage at the wet end section in the paper machine. This behavior is very much affected by the fiber population (number of fibers per gram of pulp), by the initial or refined pulp freeness (drainability of the pulp measured as Canadian Standard Freeness or Schopper Riegler degree), by the Water Retention Value (hydration and swelling ability of the pulp furnish), and by the fine content in the pulp furnish.
- Paper sheet strength along the paper machine, mainly at the wet end and press section. Sheet behavior is very much dependent on the individual fiber strength, fiber bonding, furnish contaminants (shives, sand, solid debris, etc.) and consolidation of the paper web. Individual fiber strength is related to fiber wall thickness, fibril angle, fiber deformations, and micro-fractures and the *Eucalyptus* species used.

As long as the basic physiological needs are achieved it is possible to differentiate the product to be supplied to different markets or customers. One of the most important ways to reach differentiated products is through the production

of wood with different qualities providing very different pulp fibers allowing the manufacture of different products. This is what is known as tailor making the wood to the end product. The following wood and pulp quality parameters are important drivers in the differentiation of paper products:

- Fiber population or the number of fibers per gram of pulp. The fiber population is related to the weight of each individual fiber, to fiber coarseness and to the percentage of fiber wall in the fiber volume. There are a number of fiber properties associated to fiber population and fiber coarseness: fiber wall fraction (ratio between cell wall thickness and fiber ray), Runkel index, fiber flexibility index (ratio between the lumen diameter and fiber diameter), index of fiber collapsibility, ratio fiber wall thickness and fiber perimeter, wood basic density, and fiber length. Pulps with lower fiber population show better drainage in the wet end and the paper sheets are more porous, bulkier, more permeable, and absorbent. They are very much appreciated by paper makers because they allow faster machine speeds, if they furnish enough strength to the wet paper sheet.
- Individual fiber strength. This fiber characteristic is very difficult to be measured in short fibers such as those from *Eucalyptus*. There are tests correlated to this parameter such as the zero spans, very useful for predicting pulp quality and behavior in the paper machines.
- Fiber bonding ability. This test is measured by the wet/dry zero span technique or by other equipment for bonding tests, such as the Scott bond tester. It is also related to the hemicellulose content of the fibers, fiber population, fiber drainability (CSF or SR), fiber fines content, and fiber collapsibility.
- Fiber swelling. This fiber property is affected by the pulping and bleaching operations during pulp manufacture and by the pulp hemicellulose content. Several properties are associated to the swelling of fibers: water retention value, fiber charges, fiber wall microporosity, and fiber wall microfractures.
- Fiber deformations. The deformations in the fibers are measured as curl index, fiber kinks, fiber latency, and fiber microfractures in the

cell wall. They affect fiber strength, but they provide substantial improvements in the paper sheet porosity, bulk, smoothness, and water absorption.

Eucalyptus pulps are special products in the manufacture of bulky and/or opaque papers. Today, Eucalyptus pulps are preferred raw materials in the manufacture of tissue, printing and writing, carton boards, industrial filter, impregnation based, cigarette, and many other papers. Eucalyptus fibers may be the sole fiber in the pulp furnish or to be part of a blend with other short and/or long fibers.

Tissue papers demand softness, smoothness, absorption, bulk, and the exact strength to provide machine runnability and very fast drainage in the wet end. The fibers cannot collapse because this will flatten the paper surface, the paper becomes stronger in tensile, but all the tactile properties are lost. Pulp fines are also undesirable for two reasons: fiber bonding and building up in the paper machine white water system, reflecting in drainability losses. The most indicated Eucalyptus fibers for tissue manufacture are those showing low fiber population and consequently high coarseness, low fine content, low bonding ability, low hemicellulose content, high bulk, and water absorption in the manufactured paper sheets. Fiber deformations are also important, since these deformations improve the bulk, porosity and absorption of the paper. It is important to remember that fiber deformations may be artificially created in the pulp mills. The manufacture of industrial filter papers and impregnation-based papers demand the same properties, but at different levels. This means, to go to these specialty paper markets, the differentiation must be even more pronounced. Thus the simplest way to move between very specialty markets is to work towards very high coarseness (low fiber population, high wood basic density), low hemicellulose content, and to intensify fiber deformations (by high consistency presses, fiber shredding, or pulp flash drying).

For printing and writing papers, the desirable paper properties are formation, paper strength, porosity, dimensional stability, and opacity. A higher fiber population provides improved opacity associated with lower fiber coarseness. Fiber bonding and hemicellulose and pulp fine content is

important to improve strength. However, there are limits depending on each paper machine system and operation. A very high fiber population may improve opacity and formation, but drainage at the wet end and consistency after wet presses may deteriorate and machine speed is reduced. Fiber deformation may not be so important, but may help to balance the pulp properties, since it may be created by machines. A higher hemicellulose content favors refining, bonding, consolidation of the paper web and strength properties (tensile, burst, tear, folding). An ideal pulp should have high strength at the low levels of refining. However pulp refining raises energy costs, reduces the life of refiner discs, reduces machine drainage and machine speed, increases steam consumption and a very important paper property that is dimensional stability. Definitely, the best pulps are those showing good strength at low levels of refining. Paper maker is very sensitive to this. Besides these properties, there is another wood anatomical characteristic that is very important to printing grade paper: vessel element content and vessel dimensions (especially the diameter). Large, wide, and numerous vessels are undesirable for P&W (printing and writing) papers giving a defect known as vessel picking. The paper maker needs to have special conditions to combat the vessel-picking tendency in the paper. Thus, wood with smaller and less numerous vessels is preferred.

There are many other grades of papers manufactured with Eucalyptus pulps, but generally Eucalyptus fibers are used to improve paper formation, opacity, smoothness, dimensional stability, bulk, and porosity. The Eucalyptus fiber population in the pulps is rigid and difficult to collapse an important property for paper making. There is another key driver to paper makers for using fibers: the market pulp prices of this fiber. Thanks to the low production costs, high pulping yield, and lower chemical and wood consumption, Eucalyptus pulps are generally less expensive than softwood pulps. No doubt that the production costs are also key issues for paper makers. The same are to the entire Eucalyptus pulp and paper production chain.

Eucalyptus pulps have today gained the status of the most admired fiber supply. They are growing in an unbeatable rate in the paper business. Eucalyptus pulps are versatile and may be used as the single fiber or blended with others, such

as hardwoods, softwoods or recycled fibers. Wood and fiber quality improvements due to genetic and silvicultural operations and of the conversion process may contribute to further worldwide appreciation of Eucalyptus.

3.2.1.3 *Eucalyptus* wood quality requirements for wood charcoal manufacturing and biomass fuel

Brazil has had enormous success in the utilization of Eucalyptus biomass as firewood and for charcoal production. The first biomass fuel-oriented forest plantations were based on high wood density *Eucalyptus* species, such as *E. paniculata*, *E. camaldulensis*, *E. tereticornis*, *C. citriodora*, and *C. maculata*. Wood basic density is a fundamental wood characteristic because it leads to better quality charcoal and a higher calorific value per volume of wood or charcoal. However, tree growth rate is also important in order to reach the maximum possible production of dry biomass per hectare (trunk, branches and bark). Thus, if an *Eucalyptus* species leads to high-density wood, but its growth rate is poor, the production of total biomass may not economically attractive. For this reason, the wood biomass segment has directed its efforts to the diversification of species, and hybridization. Currently, more species are being explored in the forest breeding: *E. cloeziana*, *E. pellita*, *E. urophylla*, and hybrids, such as *E. urograndis*. These species are adapted to grow in tropical regions of Brazil, where the attacks of pests and diseases are more frequent, due to higher temperature and humidity. In case that charcoal production could migrate to temperate regions, where there are other species very suitable such as *E. dunnii*, *E. viminalis*, *E. benthamii*, *E. saligna*, *E. globulus*, and hybrids.

It is important to mention that wood density is a key property, but there are other wood characteristics that are important when wood is destined for fuel purposes. The trees should be as straight as possible to favor the feeding of the charcoal ovens or biomass furnaces or chippers. The bark content is required to be as low as possible, since the wood for energy is not debarked and Eucalyptus bark has a higher percentage of minerals, lower carbon content, basic density and calorific value. Furthermore,

the high phosphorous content in the bark may make difficult the utilization of this material in the production of some grades of charcoal.

The following wood properties should be included in a forest breeding program when wood is for biomass fuel and charcoal manufacture.

- Basic Wood density and forest growth rate. It is essential to optimize these two key parameters at once. Faster growth and higher wood density are desirable with the goal of maximizing dry biomass production per hectare.
- Lignin content, lignin composition, and carbon content. The lignin calorific value is higher than that obtained from the cellulose and hemicelluloses carbohydrates. The carbon content in lignin is somewhat higher than in the wood carbohydrates. For this reason, the higher the lignin content, the higher the carbon content, and the better the wood is for fuel. The ratio syringyl/guaiacyl is another point to be considered since guaiacyl lignin is richer in carbon content than syringyl. This means that, contrary to the wood for pulping, the wood for energy the syringyl/guaiacyl ratio should be as low as possible.
- Ash content. Wood minerals do not generate heat, but they consume heat during combustion and they also reduce the carbon content of the wood and bark based on dry weight content. Both wood and bark should have minimal ash content.
- Volatile extractives. Charcoal production implies substantial dry weight losses and the usual yields when manufacturing charcoal with Eucalyptus wood varies from 30% to 40%. Many types of wood extractives are very volatile and they are lost in the exhaust flue gases during controlled combustion. Depending on the manufacturing process, the extractive content of wood and bark may affect the charcoal yield.
- Wood moisture. High-density woods have lower moisture content due to the fact that they have less open spaces or porosity to hold water. For this reason, they are easily dried for consumption as fuel raw material. High speed drying is a good quality parameter for wood selection, thus the lower the wood and bark moisture, the better is the raw material is for biomass fuel.

- Anatomical composition of the wood. It has been proven that wood that is rich in vessel elements and parenchyma cells is less recommended for charcoal manufacturing. In general, the lower the density and the quantity of these anatomical elements, the more friable and poorer quality charcoal is produced.
- Fissured and cracked logs. It is very important that the logs have good dimensional stability, with minimal cracks and fissures. These wood defects give a higher fine content in the charcoal and a lower yield as consequence, since fines have to be screened out from the charcoal to improve its quality.

Wood may be engineered and improved by selection, genetics and silvicultural operations, therefore for maximization of results, it is important to know and to understand the parameters that need to be improved. They need to show good heritability and to add value to the conversion processes and to the end-use products. Sound planning, representative sampling, high quality evaluation, and data interpretation are vital to the success of any wood quality improvement program. Many of the current successes can be attributed to the excellent opportunities offered by hybridization and cloning techniques. Wood basic density has been the most important quality parameter to predict wood quality but it is not the unique wood characteristic. Another point is that wood basic density is a very good parameter to compare wood from the same species, or with similar behavior for a given utilization. For example, even with the same wood density, two very different species of *Eucalyptus* may show very different behavior in pulping and papermaking. *E. saligna* wood with 0.5 g cm^{-3} usually shows a completely different performance than *E. robusta* wood with exactly the same wood basic density.

Definitively, there are many roads to walk in the direction to the future. Thus, future improvement programs need to be efficient and efficacious if they are to maintain continuous competitiveness of *Eucalyptus* as source of industrial raw material. These programs must not only face economic and quality issues, but also environmental and social performances. These new roads are demanding new additional challenges, and because of this, science, technology, knowledge, and goodwill are to be soundly matched.

3.2.2 Characterization of the transcriptome involved in the process of wood formation in *Eucalyptus*

Wood is formed from the vascular cambium, which is the secondary meristem, responsible for the diametric growth of the stem. When the cambial initials divide, one cell remains at meristematic status while the other is destined to become a xylem or a phloem mother cell. During differentiation, the xylem mother cells undergo an ordered series of developmental steps that include cell division, cellular expansion, and deposition of secondary cell wall, giving rise to supporting, storage, and conducting cells (Larson, 1994). The xylem transport function is carried out by a specific cell type, the vessel elements, which undergo a differentiation process characterized by successive deposition of secondary cell wall layers, culminating in PCD (programmed cell death) and autolysis.

The genetic factors controlling wood formation in *Eucalyptus* are still not fully understood. In recent years, many genes involved in wood formation have been identified by large-scale genomic approaches in *Poplars*, *Pines*, and *Eucalyptus* (Hertzberg *et al.*, 2001; Lorenz and Dean, 2002; Paux *et al.*, 2004). Hertzberg *et al.* (2001) established a hierarchical pattern of gene expression through different zones of developing xylem in *Populus* by isolating cells at different stages of xylogenesis. By microarray analysis, the authors showed that genes encoding enzymes involved in cellulose and lignin biosynthesis, as well as a large number of transcription factors and potential xylogenesis regulators are under strict control at each xylem differentiation stage. Paux *et al.* (2004) developed a targeted approach of functional genomics by the construction of a xylem-leaves subtractive library to identify genes involved in the control of *Eucalyptus* wood formation. The two main classes of ESTs preferentially expressed in xylem were related to auxin signaling through ubiquitin proteolysis, cell wall biosynthesis, and remodeling. More recently, the induction of tension in wood has been used as a model to study wood formation due to its higher cellulose content and poor lignification (Paux *et al.*, 2005; Andersson-Gunnerås *et al.*, 2006).

In the attempt to investigate the genes expressed during juvenile wood formation in *E. grandis*,

Figure 20 Biological material sampling. (a) Removal of the tree bark. (b) sampling the cambial region by scraping the tissue. (c) transversal section of *Eucalyptus* wood before removal of the bark. (d) transversal section of the *Eucalyptus* wood after removal of the bark. Bars = 100 μ m

when growth is maximized, Carvalho *et al.* (2008) produced two SAGE libraries (Velculescu *et al.*, 1995) from the cambial region of 3- and 6-year-old trees representing juvenile wood. Overall, the authors identified 444 genes involved in cellulose biosynthesis, nucleotide sugar metabolism, and lignin biosynthesis, as well other physiological processes related to wood formation. The tissue samples were collected from a half-sibling population of *E. grandis* originated from a single mother tree of a second generation of clonal seeds orchard, introduced from Coff's Harbour, Australia. A total of 40 3-year-old and 40 6-year-old trees were sampled from stands located in Itapetininga, State of São Paulo, Brazil (23°35'20" S and 48°03'11" W) at an altitude of 656 m. The 3- and 6-year-old trees were spaced at 3 \times 1.5 m and had an average height of 18 and 25 m, respectively. The cambial region of the trees were harvested in the same morning during the summer of 2003, by opening a window (20 \times 15 cm) in the bark at breast height, scraping the stem exposed tissue and the inner surface of the bark, and immediately freezing the sample in liquid nitrogen (Figures 20a and b). The stem tissue was scraped until the fibrous material below the differentiating cells was reached. The inner side of the bark was also scraped to guarantee that all the meristematic material would be represented in the SAGE libraries. This procedure was firstly used by Foucart *et al.* (2006) who showed that the cambial cells get adhered to the removed bark. Figures 20(c) and (d) also shows two transversal sections of *Eucalyptus* wood (xylem, cambial region, and

phloem) where it is possible to observe that the meristematic cells tend to follow the phloem cells when the bark is removed. Two bulks, one representing the 3-year-old trees and the other the 6-year-old trees, were made by grinding and mixing all the samples material.

The 3- and 6-year-old SAGE libraries were produced from the sequencing of 737 and 703 clones generating 22 660 and 22 024 tags, respectively. As the number of tags produced by the two libraries was very similar, the authors combined the sequencing reads from both and analyzed the data as one library representing the cambial region of juvenile *E. grandis* trees. The SAGE 2000 software extracted 43 304 tags from the sequencing data file and produced 26 958 tags with three or more copies representing 3066 unique tags or genes. From this total the authors have assigned ESTs to 657 unique tags (data not shown), 444 and produced 26 958 tags with three or more copies representing 3066 unique tags or genes. From this total the authors have assigned ESTs to 657 unique tags (data not shown), 444 with a defined function, and 213 with unknown functions. For most of the unique tags (79%) it was not possible to associate an EST or a complete cDNA due to the small number of *Eucalyptus* sequences currently available in public databases (Figure 21a).

The 444 tags that presented a tag-gene association were annotated and assigned to functional categories as defined by Rison *et al.* (2000). The most expressed categories were metabolism and energy and structure and organization of structure,

Figure 21 Distribution of the 3066 genes analyzed. (a) Tags mismatches: tags with no homology to the Eucalyptus public EST sequences, Expressed sequences: tags associated to an EST with unknown function in the GenBank, Identified genes: tags associated to an EST with a probable function defined in the GenBank. (b) Functional classification of the 444 identified genes. Functional Categories: Metabolism and energy, Cellular processes, Transport, Structure and organization of structure, and Information pathways

followed by information pathways and processes (Figure 21b).

It is important to note that among the tags in the subcategory autotrophic metabolism, there are genes associated with glycolysis, TCA cycle, alcoholic fermentation, and ATP synthesis. In nonphotosynthetic organs, carbohydrates are consumed through respiration to produce energy and carbon skeletons for cellular metabolism and biosynthesis of structural molecules, including cell wall polymers. However, the quantity of free O_2 in the cambial region might be limited by the physical barrier imposed by the bark and, also due to the O_2 consumption during respiration. Thus, a proportion of the necessary energy to secondary growth could be provided by alcoholic fermentation (Kimmerer and Stringer, 1988). The possible role of alcoholic fermentation as an alternative or principal supply of energy in juvenile *E. grandis* trees is also suggested by the presence of alcohol dehydrogenase and pyruvate decarboxylase transcripts. Other recent studies have reported the presence of transcripts

or proteins associated with anaerobic respiration during xylem formation and secondary growth (Gion *et al.*, 2005; Juan *et al.*, 2006; Ranik *et al.*, 2006).

Another interesting observation in the work of Carvalho *et al.* (2008) was the existence of tags representing light induced proteins and components of the photosystems I and II in wood forming tissues (Carvalho *et al.*, 2008). The presence of functional chloroplasts with active photosystems in the outer peridermal layers (chlorenchyma) and also in deeper stem tissues such as ray cells and pith, have been reported in many woody species (Pfanz *et al.*, 2002), what could explain the presence of transcripts related to photosynthesis in Carvalho's data. Supporting this result Celedon *et al.* (2007) also found rubisco proteins using 2D-LC-MS/MS in the same samples used in the previous study. The outer bark of the stems have a rather low permeability to gaseous diffusion, leading to accumulation of CO_2 in the intercellular air spaces, around 500–800 times higher ambient air (Pfanz *et al.*,

2002). Thus, stem photosynthesis may be an important mechanism to partially reduce the internal anaerobiosis, avoiding a further restriction to dark respiration and ATP production (Pfanz *et al.*, 2002).

3.2.2.1 Sugar-nucleotide metabolism and cell wall biosynthesis

Sugar-nucleotide metabolism provides the precursors for biosynthesis of hemicelluloses and pectins during wood formation. These precursors represent 65% and 26–36% of the primary and secondary cell walls, respectively (Mellerowicz *et al.*, 2001). The UDP-glucose dehydrogenase (UGDH) and UDP-glucuronate decarboxylase (UXS), responsible for UDP-glucuronate and UDP-xylose production, respectively, were represented by highly frequent tags (Figure 22a). However, only one UGDH tag with 22 copies was observed, while the total expression of the three UXS tags accounted for 47 copies. This expression pattern is consistent with previously reported findings pointing to a low activity of UGDH when compared to other enzymes in subsequent reaction steps in the same pathway, suggesting its function as rate limiting in the synthesis of matrix polysaccharides (Dalessandro and Northcote, 1977).

Among the UXS tags, one (TACTCGGTTG) with 27 copies is associated with the *Arabidopsis* *AtUXS3* soluble form. The other two, occurred at a frequency of 20 copies and are associated with the *Arabidopsis* *AtUX4* Golgi membrane form (Harper and Bar-Peled, 2002). A more detailed analysis of the ESTs associated with the *AtUXS4* tags revealed that the tag (TCATTATCAA) was present in both ESTs sequences distant 27 and 146 bp from the poly-A, suggesting that probably two alternative transcripts of *AtUXS4* are expressed in *E. grandis* wood forming tissues.

Besides UDP-xylose production, another important UDP-glucuronate-derived branch leads to pectin metabolism. The pectic polymers are mainly important in the primary cell wall where they comprise approximately 47% of the polysaccharides. Despite its importance in cell wall structure, only a few genes responsible for pectin biosynthesis have been identified to date.

In dicotyledonous plants, the primary cell wall consists basically of a cellulose microfibrils framework embedded in a polysaccharide matrix of pectin and cross-linked glycans (Carpita and Gibeaut, 1993). During cell extension occur modifications in the structure and composition of the cross-linked pectin-xyloglucans (Bourquin *et al.*, 2002). For example, xyloglucan endotransglycosylases (XETs) are responsible for cell wall remodeling during primary cell wall biosynthesis by cutting and rejoining the xyloglucan chains. XETs probably act during secondary cell wall deposition, as well as, by creating and reinforcing the connections between primary and secondary wall layers (Bourquin *et al.*, 2002). Despite its well-known importance in cell wall remodeling, only one XET tag with 19 copies was observed, although this result could be due to the lack of *Eucalyptus* XET ESTs publicly available. Moreover, an increased number of transcripts for pectinesterases and pectate lyases were observed during increased secondary growth in poplar tension wood (Andersson-Gunnerås *et al.*, 2006). However, under normal growth conditions experienced in our study, two pectinesterases tags at a frequency of 35 and 11 copies were observed in the cambial region library, and only one low expressed tag for a polygalacturonase (Figure 22a) in contrast to the 11 highly expressed genes identified in active poplar cambium (Geisler-Lee *et al.*, 2006).

3.2.2.2 Cellulose biosynthesis

Current models of cellulose biosynthesis involve not only CESA proteins but also membrane-associated proteins like KORRIGAN (endo-1,4- β -glucanase) and SUSY (sucrose synthase) (Joshi *et al.*, 2004). Five tags corresponding to *Eucalyptus grandis* cellulose synthase (*EgCesA*) genes were identified, one showing high similarity to the primary cell wall related cellulose synthase gene *EgCesA4*, and the other four showing high similarity to the secondary cell wall related genes *EgCesA1*, *EgCesA2*, and *EgCesA3*. Two tags (AATTGATATG and GAATCAAAAT) represented the *EgCesA1* gene, the first occurred in both ESTs sequences at a distance of 151 and 30 bp from the poly-A tail, indicating a possible alternative transcript (Figure 22a).

According to Ranik and Myburg (2006), some genes implicated in Eucalyptus secondary wall formation (*EgCesA1*, *EgCesA2*, and *EgCesA3*) have higher expression levels than those involved in primary cell wall formation (*EgCesA4*, *EgCesA5*, and *EgCesA6*) in xylem. Carvalho *et al.* (2008) observed the same transcriptional profiles for primary cell wall *EgCesA* genes. The *EgCesA4* tag shows low expression (Figure 22a) and the *EgCesA5* and *EgCesA6* tags are represented only as single-copy transcripts (Carvalho *et al.*, 2008). The higher expression of the secondary cell wall associated *CesA* genes was expected since the

The pool of UDP-glucose destined to cellulose synthesis can be produced either by UDP-glucose pyrophosphorylase or sucrose synthase. In Carvalho's study, the higher frequency of SUSY transcripts compared to UDP-glucose

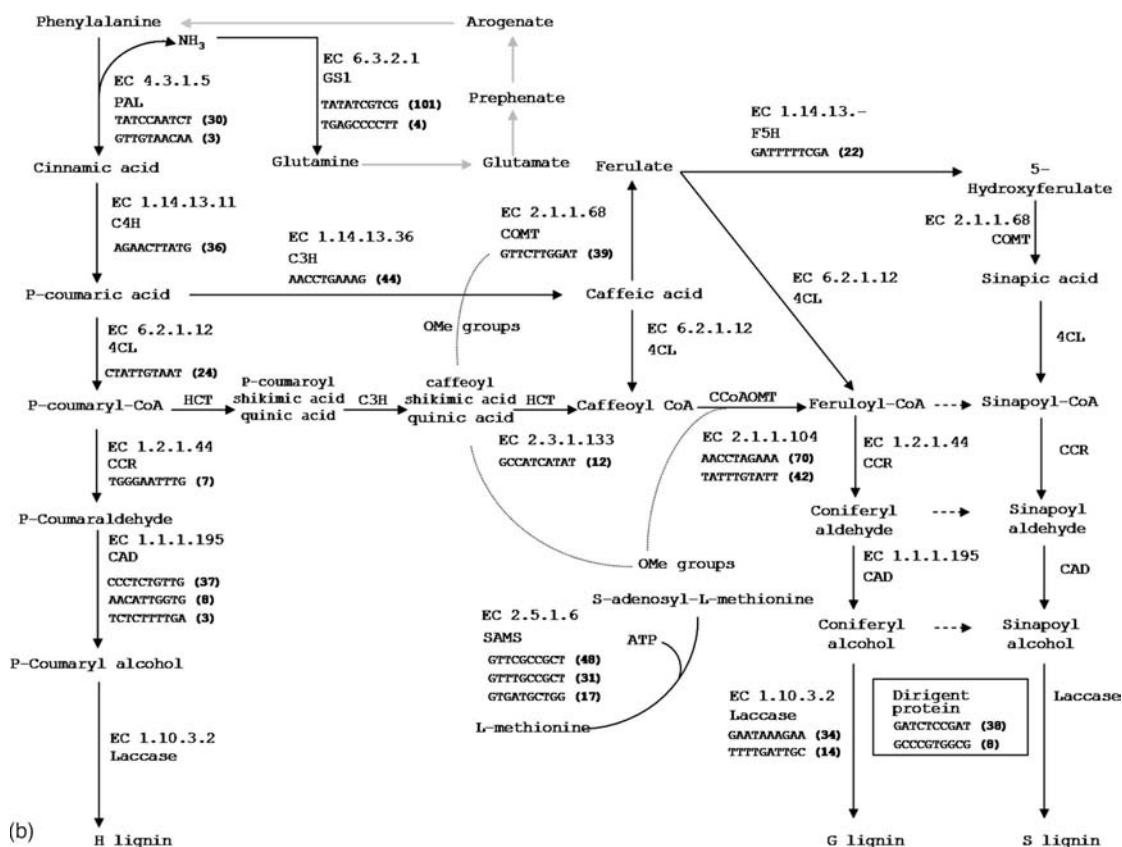

Figure 22 (Continued)

pyrophosphorylase transcripts strongly suggests that SUSY activity is probably the main source of UDP-glucose for cellulose synthesis in *E. grandis* differentiating xylem (Figure 22a). SUSY transcripts were the most abundant carbohydrate-active enzymes (CAZyme) transcripts in poplar and have been shown to be highly expressed during secondary cell wall biosynthesis in tension wood formation (Andersson-Gunnerås *et al.*, 2006). The membrane-associated SUS (SUSY) was detected in developing cotton fibers giving rise to a functional model for cellulose biosynthesis where this enzyme directly channels UDP-glucose to the membrane-bound cellulose synthesis complex avoiding competition from the cellular metabolic pool of UDP-glucose, and providing a more efficient cellulose synthesis (Amor *et al.*, 1995), especially important during active secondary growth.

3.2.2.3 Lignin biosynthesis

The phenylpropanoid pathway starts with the deamination of phenylalanine to cinnamic acid by PAL. Cinnamic acid is then converted to coumaric acid by C4H and diverted to monolignol synthesis (Figure 22b). Both enzymes from the early steps of phenylpropanoid biosynthesis were represented by highly frequent tags (Figure 22b). Both PAL genes (*AtPAL1* and *AtPAL2*) are believed to be the most important players in lignin synthesis during vascular lignification among the four *Arabidopsis* PAL genes (Raes *et al.*, 2003). The C4H tag was observed at a frequency of 36 copies and is associated with the poplar *PtreC4H2* gene, which is more xylem specific than the *PtreC4H1* and more weakly expressed in phloem (Lu *et al.*, 2006).

Only one tag representing the *E. camaldulensis* 4*CL1* gene (Figure 22b) was observed. The enzyme

4CL produces CoA thioesters of hydroxycinnamic acids, which are the precursors for H (*p*-coumaryl alcohol), G (coniferyl alcohol), and S (sinapyl alcohol) lignin subunits. One poplar 4CL gene was reported to be up-regulated in the cambial zone undergoing lignification (Hertzberg *et al.*, 2001) confirming its important role in the initial steps of lignin synthesis. Lignin polymers in angiosperm wood are composed by great amounts of G and S units while only small amounts of H units are added. This is because H units are predominantly deposited into the middle lamella and cell corners followed by G units, which are mainly laid down in the secondary wall, and S units that are deposited at the late stages of lignification (Lewis, 1999). Thus, it is expected that the key enzymes in the biosynthesis of the monolignols G and S show higher expression levels during secondary growth. The tags for COMT, CCoAOMT, and S-adenosylmethionine synthase (SAMS) showed a general higher expression level than those for 4CL and CCR (Figure 22b). These results agree with Paux *et al.* (2005), who suggested that the expression of 4CL, CCR, and CAD is under a common transcriptional control while COMT and CCoAOMT form another co-regulated transcriptional cluster. Similar expression profiles for these two enzymes was also observed by Hertzberg *et al.* (2001) supporting this hypothesis.

The determining step for the diversion of *p*-coumaryl-CoA for G and S monolignols synthesis is its conversion into *p*-coumaroyl shikimic acid/quinic acid by hydroxycinnamoyltransferase (HCT), since *p*-coumarate 3-hydroxylase (C3H) is not able to use *p*-coumaryl-CoA as substrate (Schoch *et al.*, 2001). It has been shown that *p*-coumaroyl shikimate and *p*-coumaroyl quinate are important intermediates in the phenylpropanoid pathway with HCT acting both upstream and downstream of C3H, producing caffeoyl CoA (Hoffmann *et al.*, 2004). Interestingly, the C3H tag, similar to the *Arabidopsis* CYP98A3 class of P450 gene whose expression is more evident in lignifying vascular cells (Nair *et al.*, 2002), was almost four times more expressed than the HCT tag (Figure 22b). Alternatively, C3H can also act on *p*-coumaric acid precursors producing caffeic acid, which in turns can be diverted to ferulate, by COMT, or to caffeoyl CoA, by 4CL (Figure 22b).

Although COMT was first believed to convert caffeic acid into ferulate (Dixon, 2001), it was

subsequently shown that COMT preferentially catalyzes the conversion of 5-hydroxyferulate, 5-hydroxyconiferaldehyde, and 5-hydroxyconiferyl alcohol into sinapic acid, sinapaldehyde, and sinapyl alcohol, respectively, and thus acts preferentially on ferulic acid/coniferaldehyde 5-hydroxylase (F5H) derived products (Parvathi *et al.*, 2001). A differential regulation for F5H and COMT genes is supported by recent findings obtained through a proteomic approach where F5H proteins were not found among the expressed proteins during poplar cambial regeneration, while COMT isoforms were detected at all stages (Juan *et al.*, 2006). Consistent with this previous result, our data showed that COMT transcripts expression was almost twice the F5H expression level (Figure 22b).

According to Carvalho's data, the CCoAOMT transcripts had the highest expression level of all lignin biosynthetic enzymes observed in *E. grandis* wood forming tissue (Figure 22b). This is in agreement with the results of Paux *et al.* (2004) that showed a preferential expression of this gene during Eucalyptus wood formation. CCoAOMT adds a methyl radical to caffeoyl CoA, producing feruloyl CoA in an alternative route for monolignol production (Zhong *et al.*, 1998). The importance of this alternative route was demonstrated by the down-regulation of CCoAOMT in transgenic tobacco and poplar plants leading to an altered S/G ratio and significantly decreased lignin content (Zhong *et al.*, 1998, 2000). As the number of CCoAOMT transcripts is much higher than the number for COMT, we suggest that the synthesis of S and G units is being preferentially carried out directly from caffeoyl CoA in *E. grandis*.

It is interesting to note that CCoAOMT and SAMS tags have similar high expression levels (Figure 22b), even though the presence of a common transcriptional regulatory system for both genes is still unknown. Although SAMS is a housekeeping enzyme involved in methionine metabolism, its activity occurs in xylem tissue undergoing secondary growth (Juan *et al.*, 2006). According to Cantón *et al.* (2005), SAMS might be functioning in a local providing of methyl groups consumed by CCoAOMT and COMT thus ensuring high rates of lignification.

The lignification processes also requires a large nitrogen input to support the first step

in the phenylpropanoid biosynthesis catalyzed by PAL. Extensive amounts of ammonium are liberated through phenylalanine deamination and an efficient system to recycle nitrogen is needed to prevent a severe N deficiency in plants during active lignification (Cantón *et al.*, 2005). Therefore, the authors proposed a mechanism in which the liberated nitrogen is locally recycled and re-incorporated into glutamine by GS1 (glutamine synthetase). Carvalho's results also suggest a possible role for GS1 during lignification as the GS1 tag showed high expression (101 copies), occupying the 17^o position among the 50 most expressed tags in *E. grandis* juvenile wood forming library (Table 4; Figure 22b).

The final step in lignin biosynthesis is the polymerization of monolignols that is conducted by peroxidases and laccases (Baucher *et al.*, 2003). Although the role of laccases in lignin polymerization is still a matter of debate, their importance during wood formation has been reported (Paux *et al.*, 2004). The results observed by Carvalho *et al.* (2008) corroborate a greater role for laccases in lignin polymerization during Eucalyptus wood formation due to the lack of tags representing peroxidases (Figure 22b). Supporting this idea, no significant decrease in peroxidase expression was observed in poplar tension wood (characterized by decreased lignin content), while the laccase gene lac3 is co-regulated with the lignin biosynthesis genes (Andersson-Gunnerås *et al.*, 2006). However, Hertzberg *et al.* (2001) identified two peroxidase genes up-regulated in poplar lignifying tissues, as well as, two laccases with an overlapping expression pattern, indicating specific but different roles in the polymerization process. The authors also demonstrated the induction of a dirigentlike protein coincident with lignification. Dirigent proteins can mediate the monolignols coupling mainly in the S (1) sublayer and middle lamella of lignifying secondary xylem cell walls (Burlat *et al.*, 2001). Carvalho *et al.* (2008) found one low expressed tag similar to the *Forsythia* × *intermedia* dirigent protein and a highly expressed tag similar to the *Picea glauca* dirigent protein (Figure 22b). The authors suggested that probably there are similar roles for laccases and dirigent proteins in monolignol polymerization in *E. grandis*.

The data obtained by Carvalho *et al.* (2008) offers an insight into the expression of functionally

related genes involved in cell wall biosynthesis during the first years of development of Eucalyptus, and this information is just beginning to be combined to produce an overview of the important genes for wood formation. In the near future, the information generated by functional genomics, molecular markers, transgenesis, will provide the breeders with important information to decide in the selection of the best genotypes to improve productivity, resistant to biotic and abiotic stresses, and better wood quality.

1. INTRODUCTION

Pines are a group of evergreen and resinous conifers (Table 1). The bark of the most pines species is thick and scaly, but for some it is thin and flaking. The branches are produced in regular pseudowhorls, thus appearing like a ring of branches arising from the same point (Bannister, 1965; Axelrod, 1986; Ades and Simpson, 1991; Burdon *et al.*, 1992a,b; Bergman *et al.*, 1995; Burdon and Carson, 2000). Many pines are uninodal, producing just one whorl of branches each year from buds residing at the tip of the year's new shoot growth. However, others are multinodal, producing two or more whorls of branches per year (Bannister, 1965; Burdon *et al.*, 1992a, b; Bergman *et al.*, 1995; Burdon and Carson, 2000). The spiral growth of branches, needles, and cone scales are arranged in Fibonacci number ratios. The new spring shoots are sometimes called candles; they are light colored and point upwards at first, then later darken and spread outwards (Bannister, 1965; Bergman *et al.*, 1995). These candles offer foresters a means to evaluate fertility of the soil and vigor of the trees (Burdon *et al.*, 1992a, b; Burdon and Carson, 2000).

1.1 History, Origin, and Distribution

Pines are native to most of the northern hemisphere (Burdon *et al.*, 1992a, b; Burdon and Carson, 2000). In North America, they range from

the Arctic south to Nicaragua and Hispaniola, with the highest diversity in Mexico and California (Bannister, 1965; Bergman *et al.*, 1995). In Eurasia, they range from Portugal and Scotland east to the Russian Far East, Japan, and the Philippines, and south to northernmost Africa, the Himalayas and Southeast Asia, with one species (Sumatran pine) just crossing the equator in Sumatra (Bannister, 1965; Burdon *et al.*, 1992a, b; Bergman *et al.*, 1995; Burdon and Carson, 2000). Pines are also extensively planted in many parts of the southern hemisphere (Burdon *et al.*, 1992a, b). Herein in this chapter, we describe the history, origin, and distribution of Loblolly pine (*Pinus taeda* L.), Scots Pine (*Pinus sylvestris* L.), and Monterey Pine (*Pinus radiata* D. Don).

1.1.1 Loblolly pine

Loblolly pine (*P. taeda* L.) is one of the pines native to the southeastern United States. Loblolly pine is the most important commercial timber in the southeastern United States, comprising over 50% of the standing pine in the southeast (Dvorak *et al.*, 2000). The species name, *taeda*, comes from the Latin word for "torch of resinous wood". Loblolly pine belongs to the yellow pine group and is considered the most commercially valuable forest species in the southern United States (Farjon and Styles, 1997; Dvorak *et al.*, 2000). Its native range extends from southern New Jersey to Florida, and as far west as Texas. In the Chesapeake Bay

region this rapidly growing tree thrives in the maritime forest, at the Bay's edge, in a variety of soils, including well-drained upland areas with poor nutrient concentrations to poorly drained lowland areas and abandoned fields (Farjon and Styles, 1997; Dvorak *et al.*, 2000). It prefers the Bay's relatively long, hot, and humid summers and adapts well to tree farm environments.

The name loblolly also means a "low wet place", but these trees are not limited to that specific habitat (Farjon and Styles, 1997). Other common names include: oldfield pine, due to loblolly's status as an early colonizer of abandoned fields; bull pine, due to its size; and rosemary pine, due to loblolly's distinctive fragrance compared to the other southern pines (DeCleene and DeLey, 1976; Devey *et al.*, 1999, 2002). With the advent of fire control, loblolly pines have come to dominate areas in the Deep South that were once populated with greater numbers of Longleaf pine and, especially in Florida, Slash Pine. Loblolly's rate of growth is rapid, even among the generally fast-growing southern pines. The yellowish, resinous wood is highly prized for lumber, but it is also used for pulp fibers (Libby *et al.*, 1968; Libby, 1973, 1995). This tree is commercially grown in extensive plantations, along with Slash pine.

Although Loblolly pine grows primarily in the Deep South, it ranges north along the mid-Atlantic coast to southern New Jersey, in the interior north to eastern Tennessee, and as far west as central Texas (Ledig and Conkle, 1983; Ledig, 1988, 1998). Loblolly pine is the pine of the "Lost Pines" area around Bastrop, Texas, and in McKinney

Roughs along the Texas Colorado river. These are isolated populations on areas of acidic sandy soil, surrounded by alkaline clays that are poor for pine growth.

1.1.2 Scots pine

Scots pine (*P. sylvestris* L.; Family Pinaceae) is a common tree ranging from Great Britain and Spain east to eastern Siberia and the Caucasus Mountains, and as far north as Lapland (Krugman and Jenkinson, 1974; Lanner, 1998; Lindroth *et al.*, 1999). In the north of its range, it occurs from sea level to 1000 m, while in the south of its range, it is a high altitude mountain tree, growing at 1200–2500 m altitude. In the British Isles it is now native only in Scotland, but historical records indicate that it also occurred in Ireland, Wales, and England as well until about 300–400 years ago, becoming extinct here due to overexploitation; it has been reintroduced in these countries (Krugman and Jenkinson, 1974; Lanner, 1998; Lindroth *et al.*, 1999). Similar historical extinction and reintroduction applies to Denmark and the Netherlands. Scots pine is the only pine native to northern Europe, forming either pure forests or alongside Norway spruce, silver birch, common Rowan, Eurasian aspen, and other hardwood species (Krugman and Jenkinson, 1974; Lanner, 1998; Lindroth *et al.*, 1999). In central and southern Europe, it occurs with numerous additional species, including European Black pine, Mountain pine, Macedonian pine, and Swiss pine.

In the eastern part of its range, it also occurs with Siberian pine among other trees.

Scots pine is the National tree of Scotland, and it formed much of the Caledonian forest, which once covered much of the Scottish highlands. Overcutting for timber demand, fire, overgrazing by sheep and deer, and even deliberate clearance to deter wolves have all been factors in the decline of this once great pine and birch forest (Krugman and Jenkinson, 1974; Lanner, 1998; Lindroth *et al.*, 1999). Nowadays, only comparatively small areas of this ancient forest remain, the main surviving remnants being Glen Affric, Rothiemurchus, and the black wood of Rannoch. Plans are currently in progress to restore at least some areas, and work has started at key sites. The name is derived from Latin *pinus* via French *pin* (pine). The name is sometimes mis-spelled “scotch”, a form that gives offence in Scotland and should be avoided.

Scots pine is the most widely distributed conifer in the world, with a natural range that stretches from beyond the Arctic Circle in Scandinavia to southern Spain and from western Scotland to the Okhotsk Sea in eastern Siberia. Despite this wide distribution, Scots pine forests in Scotland are unique and distinct from that elsewhere because of the absence of any other native conifers (Krugman and Jenkinson, 1974; Lanner, 1998; Lindroth *et al.*, 1999). Scots pine (*P. sylvestris*), also called Scotch pine, is an introduced species in North America, brought here from Europe probably in colonial days. Although it is used for both pulpwood and sawlogs, its principal value in the United States appears to be as a Christmas tree, as an ornamental, and for erosion control. Scots pine has been widely planted in the United States, especially in the Northeast, Lake States, Central States, and Pacific Northwest. It is now considered naturalized in parts of New England and the Lake States (Krugman and Jenkinson, 1974; Lanner, 1998; Lindroth *et al.*, 1999). The species has also been planted across southern Canada. Scots pine is the most widely distributed pine in the world. It grows naturally from Scotland almost to the Pacific Ocean and from above the Arctic Circle in Scandinavia to the Mediterranean. Its altitudinal range is from sea level to about 2440 m.

Scots pine is adapted to a wide variety of climates as indicated by its extremely large natural range. Scots pine survives in the Verkhoyansk Mountains of eastern Siberia where winter

temperatures have been recorded as low as -64°C . The primary distribution of Scots pine indicates that it is a tree of the continental climates. In some areas, it grows where the subsoil is permanently frozen (Krugman and Jenkinson, 1974; Lanner, 1998; Lindroth *et al.*, 1999). Scots pine can also survive high temperatures, and it is found at middle altitudes in the Mediterranean region.

Like most trees, the Scots pine has special mycorrhizal associations with fungi, whereby the hyphae, or threadlike filaments, of the fungi wrap around the root tips of the tree, and through this an exchange of nutrients takes place (Krugman and Jenkinson, 1974; Lanner, 1998; Lindroth *et al.*, 1999). The fungi, which are unable to make direct use of the sun's energy themselves, receive carbohydrates and sugars which the pine has produced through photosynthesis, while the tree receives certain nutrients and minerals from the fungi, which it is unable to access directly in the soil. Through this mutualistic or symbiotic relationship, both the tree and the fungi benefit and are able to grow better than they would in the absence of the other (Krugman and Jenkinson, 1974; Lanner, 1998; Lindroth *et al.*, 1999). Scots pine is known to have mycorrhizal associations with over 200 species of fungi in Scotland, and these include the chanterelle (*Cantherellus lutescens*), a relative of the common chanterelle which only occurs in the pinewoods, and the extremely rare greenfoot tooth fungus (*Sarcodon glaucopus*). Glen Affric is one of only three locations where this species has been observed in the United Kingdom.

1.1.3 Monterey pine

P. radiata (Family Pinaceae) is known in English as Monterey pine in some parts of the world (mainly in the United States, Canada, and the British Isles), and Radiata pine in others (primarily Australia, New Zealand, and Chile) (Millar, 1983, 1993, 1998). It is a species of pine native to coastal California in three very limited areas in Santa Cruz, Monterey, and San Luis Obispo Counties, and (as the variety *P. radiata* var. *binata*) on Guadalupe Island and Cedros Island off the west coast of Baja California, Mexico. It is also extensively cultivated in many other warm temperate parts of the world.

Along the California coast it has escaped from cultivation, and from there into southern coastal Oregon it shows signs of naturalizing. It has been introduced as a timber tree in vast areas of New Zealand (where it is the most common tree), Australia, Chile, Southwest Europe and South Africa (Kafton, 1985; Kinloch and Dupper, 1987; Kuang *et al.*, 1998; Karhu *et al.*, 2006). *P. radiata* grows to between 15 and 30 m in height in the wild, but up to 60 m in cultivation in optimum conditions, with upward pointing branches and a rounded top. It is closely related to Bishop pine and Knobcone pine, hybridizing readily with both species; it is distinguished from the former by needles in 3s and from both by the cones not having a sharp spine on the scales (Bollmann and Sweet, 1976; Butcher *et al.*, 1984; Burdon *et al.*, 1992a, b).

1.2 Botanical Description

1.2.1 Loblolly pine

Loblolly pine is the most important and widely cultivated timber species in the southern United States. Because it grows rapidly on a wide range of sites, it is extensively planted for lumber and pulpwood. Loblolly pine comprises over half of the standing pine volume in the south. Sonderegger pine (*Pinus* × *sondereggeri* H.H. Chapm.) is a natural hybrid between Loblolly pine and Longleaf pine (*Pinus palustris* Mill.), and occurs throughout the southeast (Neale and Sederoff, 1989; O'Brien *et al.*, 1996; Newton *et al.*, 2001). Its needles are in bundles of three, sometimes twisted, and measure 12–22 cm long: an intermediate length for southern pines, shorter than those of the Longleaf pine or Slash pine, but longer than those of the Shortleaf pine and Spruce pine. The cones are green, ripening pale buff-brown, 7–13 cm in length, 2–3 cm broad when closed, opening to 4–6 cm wide, and each scale bearing a sharp 3–6 mm spine.

Loblolly is one of the fastest growing pines, and is often chosen to use for convenient landscape screening. In urban areas, stands of loblolly are used as wind and noise barriers. The tree grows rapidly during its juvenile phase and can reach 30 m (100 ft.) tall. It is particularly prized for its straight trunk, which contains no knots for up to 9 m (30 ft.). Early colonists used the tree's resin

to boil into pitch or tar (Neale and Sederoff, 1989; O'Brien *et al.*, 1996; Newton *et al.*, 2001). Loblolly's evergreen leaf is usually between 12.7 and 25.4 cm (5 and 10 in.) long, dark green or green-yellow, with three needles per fascicle. It is monoecious and therefore bears both male and female flowers on the same plant. Male flowers are red to yellow, cylindrical, produced in clusters at the tips of branches, and on the preceding year's growth. Female flowers are yellow-purple and form on the New Year's growth. This species' cones are ovoid, not precisely oval, and they are usually between 7.62 and 15.24 cm (3 and 6 in.) long, with sharp spines on the scales (Neale and Sederoff, 1989; O'Brien *et al.*, 1996; Newton *et al.*, 2001). The bark of the juvenile tree changes from a dark brown to a brownish-red color, and as the tree matures, the bark separates into deeply furrowed plates, sometimes 5.08 cm (2 in.) thick. Although the bark used to be discarded after the tree was harvested, now it is often sold as mulch. Loblolly's needles also are valued as mulch around plants that thrive in acidic soils, such as azaleas and camellias (Neale and Sederoff, 1989; O'Brien *et al.*, 1996; Newton *et al.*, 2001).

One of the most common trees on Assateague Island, loblolly can grow up to 30 m (100 ft.) tall and up to 0.9 m (3 ft.) in diameter; however, along the coast it seldom rises more than 15 m (50 ft.). Because of the shade from these trees, loblolly wood will have few smaller trees or shrubs (Pederick, 1970; Plessas and Strauss, 1986; Peters, 1990; Perry, 1991; Price *et al.*, 1998). Often during a storm you will find ponies and deer taking refuge in the wide spaces beneath them. Loblolly pine woods are also home to the Delmarva fox squirrel, and on the refuge, you will spot squirrel houses attached to these trees. Loblolly's yellow-green needles can become up to 22.86 cm (9 in.) long and usually grow in bunches of three. Cones up to 22.86 cm (9 in.) long can be found, each with scales tipped with prickles. Loblolly pine is a large evergreen tree that reaches heights of 90'–110'. It has a long, clear bole that is occasionally buttressed, ascending limbs, and a rounded, spreading crown (Pederick, 1970; Plessas and Strauss, 1986; Peters, 1990; Perry, 1991; Price *et al.*, 1998). Young trees retain lower branches much longer than Slash or Longleaf pines. The leaves are needlelike, 4'–9' long, and are borne in fascicles of three. They have a slight bluish-green

tinge, are stiff, and sometimes slightly twisted (Pederick, 1970; Plessas and Strauss, 1986; Peters, 1990; Perry, 1991; Price *et al.*, 1998).

The fruits of Loblolly pine are dark brown, oblong to cylindrical cones, about 3''–6'' long, sessile, and persistent on the trees for several seasons. Loblolly pine produces a large number of cones every year. The bark is grayish brown and furrowed with elongate, broad, irregular plates (Pederick, 1970; Plessas and Strauss, 1986; Peters, 1990; Perry, 1991; Price *et al.*, 1998). Young twigs are reddish brown and scaly. Buds at the ends of branches are much thinner than associated Slash and Longleaf pine. Loblolly pine prefers acid soils and full sun, but will adapt to a variety of sites, including fertile, upland fields, moist forests, or with mixed hardwoods. It is often found in association with Shortleaf pine (*Pinus echinata*).

1.2.2 Scots pine

Scots pine grows up to 25 m in height when mature, exceptionally to 35–40 m on a very productive site (in Estonia, are some trees ca. 46 m in height, at age 220 years in 2006). The bark is thick, scaly dark gray-brown on the lower trunk, and thin, flaky, and orange on the upper trunk and branches (Righter and Duffield, 1951; Roy, 1966; Sigg, 1987; Sedjo, 1999; Rogers *et al.*, 2006). The habit of the mature tree is distinctive due to its long, bare, and straight trunk topped by a rounded or flat-topped mass of foliage. On mature trees the leaves ("needles") are a very attractive blue-green, 3–5 cm long and occur in pairs, but on young vigorous trees the leaves can be twice as long, and occasionally occur in 3s and 4s on the tips of strong shoots. The cones are pointed ovoid in shape and are 3–7 cm in length (Righter and Duffield, 1951; Roy, 1966; Sigg, 1987; Sedjo, 1999; Rogers *et al.*, 2006). Over 100 varieties have been described in the botanical literature, but only three are now accepted, the typical var. *sylvestris* from Scotland and Spain to central Siberia, var. *hamata* in the Balkans, northern Turkey and the Caucasus, and var. *mongolica* in Mongolia and adjoining parts of southern Siberia and northwestern China. One other variety, var. *nevadensis* in southern Spain, may also be distinct.

After the end of the last Ice Age, approximately 10 000 years ago, Scots pine, like other trees, spread

northwards again from continental Europe into Britain. As the climate continued to warm, it spread into much of northern Scotland, reaching a maximum distribution about 6000 years ago, before declining about 4000 years ago for reasons that are not entirely understood (Righter and Duffield, 1951; Roy, 1966; Sigg, 1987; Sedjo, 1999; Rogers *et al.*, 2006). Today, Scots pine has a natural range confined to the highlands in Scotland, with the native pinewoods covering approximately 17 000 hectares in a number of separate, isolated remnants—just over 1% of the estimated 1 500 000 hectare original area. In many of the remnant areas, Scots pine is growing on north-facing slopes, but the exact reason for this is not clear; the generally wetter conditions of such northerly aspects may have provided protection from fire, which was used to clear the forest in past centuries (Righter and Duffield, 1951; Roy, 1966; Sigg, 1987; Sedjo, 1999; Rogers *et al.*, 2006).

Scots pine is unusual amongst conifers in having a number of different mature growth forms, ranging from tall and straight trunked with few side branches, to broad, spreading trees with multiple trunks. Eleven different growth forms, or habit types, have been identified for Scots pine in Scotland, and many of these can easily be seen in the pinewood remnants. Young stands of Scots pine display the characteristically conical shape of conifers, but as the trees mature, this gives way to the flat- or round-topped shapes that are typical of the pines in the ancient Caledonian Forest remnants (Righter and Duffield, 1951; Roy, 1966; Sigg, 1987; Sedjo, 1999). The bark of the Scots pine is also quite variable, with the young bark on small branches being papery thin and often orange-red in color. The bark on the trunk of a mature Scots pine can vary from gray to reddish brown and forms layered plates or flakes up to 5 cm thick, with deep fissures in between. Several species of lichen commonly grow on the bark. The needles grow in pairs, are blue-green in color and are about 5 cm in length. They normally remain on the trees for 2–3 years, with the old needles turning yellow in September or October before they shed. Drops of sticky resin often cover the tree's buds, and also provide a natural preservative for the wood. If a Scots pine tree dies while it is still standing, the skeleton can persist for 50 or even 100 years before falling down; the high resin content in the sap makes the wood very slow to

decay (Righter and Duffield, 1951; Roy, 1966; Sigg, 1987; Sedjo, 1999; Rogers *et al.*, 2006).

Male and female flowers occur on the same tree. They appear in May with the females on the tips of the higher and more exposed branches and the males clustered together, often *en masse*, on the branches just below. Pollination is by wind, and fertilized female flowers take 2 years to become a fully grown cone. The cones ripen in April, opening while they are still on the tree, and the tiny winged seeds, each weighing 0.005 g, are dispersed by the wind. Cone production is variable, with good seasons, in which a mature tree can produce 3000 cones, occurring every 3–5 years, while in between a tree will produce few cones or none at all (Righter and Duffield, 1951; Roy, 1966; Sigg, 1987; Sedjo, 1999; Rogers *et al.*, 2006). The seeds are generally carried as far as 50–100 m from the parent tree, although in some situations, especially when there is snow on the ground and a frozen top layer forms, the seeds have been known to travel several kilometers over the smooth, icy surface.

The seeds require a high level of light to germinate and grow, so seedlings are found in open areas and clearings; as a shade-intolerant species, Scots pine does not regenerate under its own canopy (Righter and Duffield, 1951; Roy, 1966; Sigg, 1987; Sedjo, 1999; Rogers *et al.*, 2006). In Europe, Scots pine grows on a wide variety of soil types. In Scotland, it is found on the most ancient rocks and also on the most recent glacial deposits. The cool, humid climate of Scotland, along with the nature of the parent material, which is usually siliceous and acidic, frequently results in a deep litter and raw humus layer. The soils exhibit various degrees of podzolization. Scots pine grows well on these soils but best growth is on freely drained sands and gravels, often on knolls and terraces. These soils have only a thin layer of raw humus and are weakly podzolized. Although Scots pine grows on peat land in certain areas, usually it is badly stunted (Righter and Duffield, 1951; Roy, 1966; Sigg, 1987; Sedjo, 1999). Studies of the mineral nutrient content of the foliage of several Scots pine provenances at three sites in Michigan show that Scots pine has evolved an efficient mechanism to extract nutrients. Significant differences were found among seed sources in their ability to accumulate nitrogen, phosphorus, sodium, magnesium, and boron. Magnesium was one of the key minerals in Scots

pine nutrition at all three sites. The faster-growing seed sources accumulated higher levels of foliar magnesium (Righter and Duffield, 1951; Roy, 1966; Sigg, 1987; Sedjo, 1999).

Scots pine is native to Europe and Asia. From the British Isles and Scandinavian peninsulas through central Europe south to the Mediterranean and east through eastern Siberia, Scots pine can be found at varying elevations. Scots pine was introduced to North America by European settlers and has long been cultivated, especially in the eastern United States and Canada. It is adaptable to a wide variety of sites and accordingly, has been widely planted for both Christmas tree and ornamental purposes (Righter and Duffield, 1951; Roy, 1966; Sigg, 1987; Sedjo, 1999). Although plantations have been established in the United States for the purpose of producing forest products, the species does not perform as well as in its native habitat.

1.2.3 Monterey pine

Monterey pine trees are 15–30 m tall, 30–90 cm in diameter, contorted to straight; crown broadly conic, becoming rounded to flattened. Their bark is gray to reddish brown, deeply V-furrowed, furrow bases red, ridges irregularly elongate-rectangular, and their flattened surfaces scaly (Sweet and Bollmann, 1976; Strauss and Conkle, 1986; Strauss and Doerksen, 1990). Their branches are level to down-curved or ascending, poorly self-pruning; twigs slender, red-brown, sometimes glaucous, aging gray, and rough. Monterey pine buds are ovoid to ovoid-cylindric, red-brown, ca. 1.5 cm, resinous. They have needles with 2 (var. *binata*) or 3 (type variety) per fascicle, spreading-ascending, persisting 3–4 years, (8)9–15(20) cm × 1.3–1.8(2) mm, straight, slightly twisted, deep yellow-green, all surfaces with fine stomatal lines, margins serrulate, apex conic-subulate; sheath 1.5–2 cm, base persistent (Strauss *et al.*, 1993; Smith and Devey, 1994; Spencer *et al.*, 1998). Seed cones mature in February, 2 years after pollination, mostly serotinous and persistent 6–20 (–40) years, numerous, solitary to whorled, spreading to recurved, curved, mostly asymmetric (usually symmetric in var. *binata* and occasionally so in var. *radiata*), ovoid before opening, broadly ovoid when open,

7–15 cm, yellow-brown, lustrous, scales rigid, stalks to 1 cm; apophyses toward outer cone base mostly increasingly mammillate (but not in var. *binata*), those on inward cone side and middle and apex of cone more level; umbo central, mostly depressed, with small central boss or occasionally with slender, deciduous prickle. Seeds are compressed–ellipsoid; body ca. 6 mm, dark brown; wing 20–30 mm $2n = 24$ (Fielding, 1957; Forde, 1966; Falkenhagen, 1991).

In the wild, Monterey pine in California is seriously threatened by an introduced fungal disease, pine pitch canker, caused by *Fusarium circinatum*, while var. *binata* on Guadalupe Island is critically endangered (less than 100 surviving trees) by uncontrolled grazing by goats released long ago on this nearly uninhabited island. The forests associated with Monterey pine are associated with other flora and fauna of note. In particular, the pine forest in Monterey, California was the discovery site for Hickman's potentilla, an endangered species (Storer *et al.*, 1999; Sutton, 1999; Siregar and Sweet, 2000). *Piperia yadonii*, a rare species of orchid is endemic to the same pine forest adjacent to Pebble Beach. Nearby in a remnant pine forest of Pacific Grove, is a prime wintering habitat of the Monarch butterfly (Hiebert and Hamrick, 1983; Griffin and Lindgren, 1985; Gorman *et al.*, 1992; Hillyard, 1997; Gordon *et al.*, 1998; Hodge and Dvorak, 2000). Monterey pine, *P. radiata*, is the most widely planted pine in the world. This species has become important for lumber and paper in Australia, New Zealand, Spain and large areas in Africa and South America. Rapid growth and attractive foliage quickly provide variety and contrast in the landscape. In their native habitat along the Pacific coast, Monterey pines are famous for their wind-swept, picturesque shape.

Monterey pine is an adaptable tree, but it does have specific cultural requirements. Temperatures below freezing for only a few hours are damaging to this species. Temperatures above 100 °F cause needle scorch and damage to new shoots. In the summer, Monterey pine is adapted to cool, foggy conditions. The tree's needles collect fog, dripping as much as 3.81 cm (1½ in.) per week to the root system. Monterey pine is susceptible to air pollution, particularly ozone injury. Monterey pine grows best in acidic, well-drained soils. A 10.16 cm (4 in.) layer of organic matter, such

as wood chips, is very beneficial. This species does not thrive on shallow soils and is prone to blow down on such sites. Monterey pine is considered susceptible to a wide range of pests, with bark beetles and root rots the most serious tree killers (Copes, 1981; Cromer *et al.*, 1982; Cotterill *et al.*, 1987; Cylinder, 1995; Cato and Richardson, 1996; Cato *et al.*, 2001). A total of 56 species of insects and 18 diseases are listed as attacking Monterey pine. Characteristics of Monterey pine include the following: (1) leaf: evergreen needles, 10.16–15.24 cm (4–6 in.) long, 3 per fascicle, slender; shiny green; persist 3 years, (2) flower: monoecious; male cones in yellow spikes; female cones dark purple, (3) fruit: egg shaped, 7.62–15.24 cm (3–6 in.) long, asymmetrical (especially at the base), shiny brown, often clustered in dense whorls, serotinous (remain closed on the tree for many years); cone scales thick and rounded, tipped with a small prickle, (4) twig: slender and dark orange, (5) bark: mature bark is dark reddish-brown; thick with deep ridges and furrows, (6) form: straight trunk with irregular, open crown, 15–30 m (50–100 ft.) tall and 0.3–0.9 m (1–3 ft.) in diameter; cone clusters are often conspicuous on branches and trunk.

1.3 Economic Importance

1.3.1 Loblolly pine

Loblolly pine is the most commercially important pine of the southeast where it is dominant on approximately 29 million acres and makes up over one-half the standing pine volume. This pine cannot survive the occasional severe winters of USDA zone 5 but has a solid hold on most of the southern forest. It is the most common plantation pine in the southern forest, but has a problem with fusiform rust disease (*Cronartium quercuum*).

Loblolly pine is used by human for furniture, pulpwood, plywood, composite boards, posts, poles, pilings, crates, boxes, pallets. Loblolly is also planted to stabilize eroded or damaged soils. It can be used for shade or ornamental trees, as well as bark mulch.

Loblolly pine is also used by different animals. White-tailed deer (*Odocoileus virginianus*), gray squirrel (*Sciurus carolinensis*), fox squirrel (*Sciurus niger*), bobwhite quail (*Colinus virginianus*), and

wild turkey (*Meleagris gallopavo*) all utilize both pure and mixed loblolly stands for shelter. Red-cockaded woodpeckers (*Picoides borealis*) also use these trees for foraging habitat and nesting, as do a variety of other bird species such as the pine warbler (*Dendroica pinus*), brown-headed nuthatch (*Sitta pusilla*), and Bachman's warbler (*Vermivora bachmanii*). Seeds are also eaten for food by songbirds and small mammals. Standing dead trees are frequently used for cavity nests by woodpeckers.

1.3.2 Scots pine

Scots pine is an important tree in the forestry industry. The wood is used for pulp and timber products. A seedling stand can be created by planting, sowing, or natural regeneration. Commercial plantation rotations vary between 50 and 120 years, with longer rotations in north-eastern areas where growth is slower. In Finland, Scots pine was used for making tar in the preindustrial age. There are still some active tar producers, but mostly the industry has ceased to exist. The wood is pale brown to red-brown, and used for general construction work. Scots pine has also been widely planted in New Zealand and much of the colder regions of North America; it is listed as an invasive species in some areas there, including Ontario and Wisconsin (Laitakarai, 1927; Heit, 1969; Lemmien and Botti, 1974).

A number of rare and special plants are particularly associated with the pinewoods of the Caledonian forest, and these include twin-flower (*Linnaea borealis*), one-flowered winter-green (*Moneses uniflora*), and orchids such as creeping ladies tresses (*Goodyera repens*) and lesser twayblade (*Listera cordata*). The shade provided by the canopy of mature Scots pines provides a good habitat for blueberries (*Vaccinium myrtillus*) and cowberries (*Vaccinium vitis-idaea*), and dense carpets of these cover the forest floor in many areas. They also play a successional role in the development of the hummocks that are commonly found in the pinewoods. These hummocks form over extended periods of time in the shade of the trees, when lichens and mosses colonize boulders or tree stumps. As these lower plants grow, humus or organic matter builds up, and this allows the blueberries and cowberries to become

established. Eventually a living mat of vegetation is formed, completely covering the underlying boulder or stump, and creating the gently rounded, hummocky forest floor, which is characteristic of many of the native pinewood remnants of the Caledonian forest (Laitakarai, 1927; Mosher and Wilson, 1977; Heit, 1969; Lemmien and Botti, 1974).

Like all trees, Scots pine attracts the attention of various insects. Some of these live in the fissures between the plates or flakes of the tree's bark, and these form a food source for birds such as the crested tit (*Parus cristatus*) and the treecreeper (*Certhia familiaris*), which specialize in winking them out of the cracks and crevices. Larvae of the pine weevil (*Hylobius abietis*) burrow into the wood of the tree, and other insects live on the pine's foliage—aphids suck the sap, and caterpillars of species such as the sawfly (*Neodiprion sertifer*) and pine looper moth (*Bupalus piniaria*) eat the needles (right). Wood ants (*Formica aquilonia*) feed on these caterpillars, thereby helping to protect the trees from defoliation. These ants live in large social colonies, and their mounds of fallen pine needles and forest detritus are a characteristic feature of the pinewoods. A variety of birds are associated with Scots pine in Scotland, ranging from common insect- or seed-eating species like the chaffinch (*Fringilla coelebs*) and siskin (*Carduelis spinus*) to large raptors such as the golden eagle (*Aquila chrysaetos*). Black grouse (*Tetrao tetrix*) and capercaillie (*Tetrao urogallus*) both live in the pinewoods and eat the buds and shoots. The capercaillie became extinct in Scotland in the 18th century, but was successfully reintroduced from Scandinavia in 1837 and is primarily associated with the native pinewoods today. The only bird that is endemic to the United Kingdom (i.e., found here and nowhere else in the world) is the Scottish crossbill (*Loxia scotica*), which is confined to the pinewoods (Laitakarai, 1927; Mosher and Wilson, 1977; Heit, 1969; Lemmien and Botti, 1974). It is sometimes called the "Scottish parrot" because of its crossed mandibles, which it uses to pry open the tightly fitting scales of the Scots pine's cones. The seeds inside form the mainstay of the diet for this rare bird.

Mammals associated with the pinewoods include the red squirrel (*Sciurus vulgaris*), which also extracts and eats the seed from pine cones while they are still on the trees; mice and voles,

which feed on pine seeds which have fallen to the ground, and the pine marten (*Martes martes*), which eats voles, red squirrels, and small birds, and relishes blueberries in late summer. Larger mammals found in the pinewoods include the wild cat (*Felis silvestris*), badger (*Meles meles*), fox (*Vulpes vulpes*), roe deer (*Capreolus capreolus*), and red deer (*Cervus elaphus*). Both roe and red deer browse on Scots pine seedlings, eating the needles and leader shoot of young trees, and the overgrazing pressure from their expanded numbers in the last 150 years has prevented the natural regeneration of the native pinewoods throughout the Highlands (Laitakarai, 1927; Mosher and Wilson, 1977; Heit, 1969; Lemmien and Botti, 1974). Red deer also damage or kill sapling Scots pines by debarking or thrashing them with their antlers, particularly in late spring when the new season's antlers are shedding their velvet. In a natural, healthy forest ecosystem, the deer numbers would be in balance with the regenerating trees in the forest, but the imbalance in our pinewoods has created a "generation gap" in Scots pine, with no trees younger than 150 years in most locations, until fencing or intensive deer-culling measures were initiated in the last 10–20 years.

In the past, pinewoods supported a wider range of large mammals, including the wild boar, European beaver (*Castor fiber*), lynx (*Felis lynx*), moose (*Alces alces*), brown bear (*Ursus arctos*), and the wolf (*Canis lupus*), but in Scotland these have all been extirpated—the wolf was the last to disappear, when the last individual was shot in 1743. Little known until relatively recently, the native pinewoods of the Highlands have become the subject of various restoration and regeneration programs, and the future prospects for this unique part of Scotland's natural heritage now look better than they have done for centuries. Many of the best remnants of the pinewoods have active restoration measures underway in them and research projects are elucidating more of the interconnections and relationships that make up this boreal forest ecosystem. In Europe and throughout several countries in Asia, Scots pine is an important species of high economic value. Forest stands containing Scots pine are managed to produce pulpwood, poles, and sawlogs from which dimension and finish lumber is produced. Logs from trees of large diameters are processed into veneer and used in manufacturing plywood.

The species is also valued as an ornamental and landscape plant and has been widely planted in parks and gardens (Mosher and Wilson, 1977; Heit, 1969; Lemmien and Botti, 1974).

As a Christmas tree Scots pine is probably the most commonly used species in the United States. Because of its ease of planting, generally high planting survival and favorable response to plantation culture it has been widely planted throughout much of the eastern United States and Canada. For several years it was the favorite species of large eastern wholesale growers because of its excellent harvesting and shipping qualities. It is also a preferred species for many choose and cut growers in much of the eastern and central United States. When established in plantations usually 6–8 years are required to produce a 2.1–2.4 m (7–8 ft.) tree. The tree requires annual shearing, usually beginning at the second or third year following planting and continuing on through the year of harvest. Scots pine is host to a number of insect and disease problems, and continued protection from foliage and stem damaging agents is necessary. The species is not demanding with respect to fertility or moisture and supplemental fertilization or irrigation is not considered necessary. As a Christmas tree, Scots pine is known for its excellent needle retention and good keepability. It resists drying and if permitted to become dry does not drop its needles. When displayed in a water-filled container it will remain fresh for the normal 3–4 week Christmas season (Laitakarai, 1927; Mosher and Wilson, 1977; Heit, 1969; Lemmien and Botti, 1974). Like all natural trees it is readily recyclable and has many different uses following the Christmas holidays.

1.3.3 Monterey pine

Monterey pine is a fast-growing tree, adaptable to a broad range of soil types and climates, though does not tolerate temperatures below about -15°C . Its fast growth makes it ideal for forestry; in a good situation, *P. radiata* can reach its full height in 40 years or so. It was first introduced into New Zealand in the 1850s; today, over 90% of the country's plantation forests are of this species. This includes the Kaingaroa forest on the central plateau of the North Island, which is the largest planted forest in the world. Australia also has

massive radiata pine plantations; so much so that many Australians are concerned by the resulting loss of native wildlife habitat. A few native animals, however, thrive on *P. radiata*, notably the yellow-tailed black cockatoo which, although deprived of much of its natural diet by massive habitat alteration, feeds on *P. radiata* seeds. *P. radiata* has also been introduced to the Valdivian temperate rain forests of southern Chile, where vast plantations have been planted for timber, again displacing the native forests. In areas such as New Zealand this tree has become naturalized, and is considered a weed in the native forest habitat where it has escaped from plantations.

1.4 Traditional Breeding: Breeding Objectives, Tools and Strategies, and Achievements

1.4.1 Loblolly pine

Loblolly pine is found throughout much of the southeastern United States from New Jersey to central Florida and west into Tennessee, Kentucky, Texas, and Oklahoma. It grows primarily in coastal plains and some Piedmont regions. This is an easily seeded, fast-growing member of the yellow pine group and is an aggressive invader in fallow fields. It is widely grown in plantations for commercial timber production, but also has been planted to help stabilize soil and reduce erosion or as a noise and wind barrier. Loblolly pine has also been planted in mine reclamation areas; and due to its high litter and biomass productivity, it is being studied as a possible alternative source for energy. The wood, which is marketed as southern yellow pine, is primarily used for pulp and paper but also for lumber and plywood. It may be sold interchangeably with Shortleaf pine.

Loblolly pine stands are important for numerous wildlife species. The trees provide habitat for many animals, including white-tailed deer, wild turkey, gray squirrels, rabbit, quail, and doves. Many songbirds feed on the seeds and help propagate the trees through seed dispersal. Red crossbills depend on Loblolly pine seeds for up to 50% of their diet. Other birds that frequent the trees include pine warblers, Bachman's warblers, and brown-headed nuthatches. Osprey and bald eagles often nest in tall loblolly trees. Two

endangered species that also use these pines are fox squirrels, which eat the cones, and red-cockaded woodpeckers, which will sometimes nest in old growth trees.

1.4.2 Scots pine

Scots pine is the most widely planted pine introduced in North America. It is also the preferred large-volume Christmas tree in the United States—approximately 30% of the 35 million Christmas trees harvested annually are Scots pine. Because it survives on poor droughty sites, Scots pine has been used to control erosion in many areas. However, the poor vigor of many of these stands on dry, infertile sites has made them susceptible to serious insect attack and many of them have little potential to produce timber. Scots pine has also been used to a large extent in ornamental plantings. It grows better than red pine on compacted clay soils frequently found around home sites. Because Christmas tree plantations are a ready source of trees, many trees are removed from these plantations as ornamental stock. Scots pine has also been planted along roadsides throughout the Lake States. They are similar in fiber and wood characteristics to red pine and are usable for both pulpwood and saw logs (Rudolph and Lemmien, 1959; Schreiner *et al.*, 1962; Steinbeck, 1966; Skilling and Nicholls, 1974; Skilling, 1981).

In Europe, seed source studies on Scots pine go back almost 200 years, and the literature on genetic variation is large. In the United States, an international seed source trial was conducted in 1938. This trial included trees grown from seed collected in Scandinavia and north-central Europe. In 1961, seeds from 162 natural stands and 24 plantations in Europe and Asia were out-planted in 12 test plantations in Michigan. The results of these seed source studies show the extreme importance of beginning with the correct seed source. The fastest-growing varieties from central Europe grew 2.5 times as tall and produced 15 times as much wood as the slowest-growing variety. In Michigan, the variety *carpatica* from eastern Czechoslovakia was most suitable for timber production because of its fast growth and good stem form. The next best was variety *haguenensis* from Belgium, Vosges Mountains of

France, and adjacent West Germany. However, these varieties may perform poorly in other parts of the United States. Information on performance of many seed sources is now available for most of the Lake States and the Northeast (York and Littlefield, 1942; Wright and Bull, 1963; Wright *et al.*, 1966a, b; Wright and Wilson, 1972; Skilling, 1981).

This difficulty appears to be partly due to grazing by deer and domestic animals. Successful regeneration has been achieved, however, with the uniform or shelter wood compartment system, which also appears to be successful in the Scandinavian countries. The best regeneration is found in stands with the following characteristics: large seed supply, open or light tree canopy, light understory ground cover, and exposed mineral soil or no continuous layer of raw humus. When scleroderris canker (*Gremmeniella abietina*) is present in the Scots pine over-story, the advance reproduction can be completely eliminated. Although Scots pine is primarily a monoecious species, some shoots, branches, and even entire trees are predominantly of one sex. Male flower primordia are formed in late summer at the base of the bud that will make the next year's growth. During the winter their presence can be noted as a slight swelling, and the preferred male catkins are easily visible if a bud is dissected. About 2 weeks after growth begins in the spring, the male catkins enlarge to 0.6–0.7 cm (0.2–0.3 in.) long and shed pollen. The male catkins are borne at the base of the twigs, replacing leaf clusters. They are most common in the lower part of the crown and on short lateral twigs. Because they replace leaves, an excess of pollen production can lead to sparse foliage. A Pennsylvania breeder who selected for early flower production for two generations obtained a variety that produced plentiful pollen but few needles, and it was worthless as a Christmas tree (Laitakarai, 1927; Mosher and Wilson, 1977; Heit, 1969; Lemmien and Botti, 1974).

Female flower primordia are also formed in late summer but are microscopic. They are borne at the tips of buds for the next year's growth. There may be one, two, or three on a single bud. They first become visible after the buds expand in the spring. The primordia enlarge into female flowers or strobili about 2 weeks after growth begins in the spring, at a time when the new

growth has completed 75% of its elongation for the season. Because of this, shearing of the outside branches such as is practiced by Christmas tree growers removes all female flowers. Indeed, trees sheared in June will not produce seed for the next 3.5 years. Flowering occurs in late May or early June. On any one tree nearly all pollen is shed and nearly all the female flowers are receptive during the same 2- or 3-day period. In any one stand most trees flower within a day or two of each other. Trees of different provenances may differ in blooming time by several days, however; trees of northern provenances bloom the earliest (York and Littlefield, 1942; Wright and Bull, 1963; Wright *et al.*, 1966a, b; Skilling and Nicholls, 1974; Skilling, 1981).

Pollen production tends to be concentrated on short lateral twigs in the lower half of a tree crown. Female flowers are borne on the most vigorous shoots. They tend to be concentrated on upper branches but may occur in any part of the crown receiving full sunlight. Pollination occurs in early summer, at a time when the female strobili are from 0.6 to 0.7 cm (0.2–0.3 in.) long. Shortly after pollination, the scales of the female strobili thicken, and the pollen grains germinate and send out a short pollen tube. At this time the female strobili become reflexed instead of pointing forward (Laitakarai, 1927; Mosher and Wilson, 1977; Heit, 1969; Lemmien and Botti, 1974). For the next 12 months the germinated pollen remains dormant and the female strobili grow little. A little more than a year after pollination, the germinated pollen grains renew growth and fertilize the ovules. In June, soon after fertilization, the conelets rapidly elongate and reach full size by early summer. Seeds mature and cones ripen in early October. The cones require alternating periods of dry and wet weather to open and shed few seed until early winter. Indeed, many seeds are retained on the tree until early spring.

Seeds from any one tree can be sorted visually by color into those that are full and those that are empty—empty seeds are much lighter in color than full ones. On any one tree the full seeds are fairly uniform in color and size, but both traits vary considerably from tree to tree. Trees from the same stand may produce seeds ranging from tan to almost black and from all one color to speckle. Seed size varies in a geographic pattern—seeds from the extreme northern latitudes are half the

size of those from the southern part of the range. Individual trees in Michigan, under favorable growth conditions, begin to produce male and female flowers from 5 to 8 years, although the average is between 10 and 15 years.

Form is as much a matter of site as of variety. On some sites most trees grow crooked whereas on other sites trees of any variety are usually straight. The tendency for a variety to be straight or crooked depends on its susceptibility to a particular pest or other damaging agent, and on the presence of that pest or damaging agent in that locality. For example, when the Zimmerman moth (*Dioryctria zimmermani*) is present in high numbers, Greek trees, which are generally not attacked, are straight, while Belgian trees, which are very susceptible, are very crooked. Where pine grosbeaks are present in large numbers, the Belgian trees, which are resistant to this pest, are straight whereas trees of the Riga variety are likely to be crooked. Poor quality sites seem to have a larger number of pests and a larger number of poorly formed trees than good quality sites. To promote closer branching and denser crowns for Christmas tree production, the trees are sheared by removing the tips of all the new shoots. Following shearing, the leaf fascicles near the cut ends develop adventitious buds. These buds are not formed if shearing is done during late summer (York and Littlefield, 1942; Wright and Bull, 1963; Wright *et al.*, 1966a,b; Wright and Wilson, 1972; Skilling and Nicholls, 1974; Skilling, 1981).

In nature, Scots pine does not reproduce vegetatively. It is not difficult, however, to graft scions from the larger trees onto potted understock of Scots pine. In a Swedish study, cuttings from young seedlings (50–100 days old) rooted readily, but cuttings from shoots of 3-year-old plants rooted poorly. Scots pine shows tremendous variation in yield, both by site and by geographic seed source. In seed source tests, some varieties grew 2.5 times as fast as others on the same site (Wright and Bull, 1963; Wright *et al.*, 1966a,b; Steinbeck, 1966; Skilling and Nicholls, 1974; Skilling, 1981). The average height of 150-year-old trees in Scotland is from 13.7 to 16.8 m (45–55 ft.). On well-drained sites, an occasional tree as tall as 22.9 m (75 ft.) is found. In a Michigan study in which dominant crop trees were released, the released trees averaged 13.7 m (45 ft.) in height

and 18 cm (6.9 in.) in d.b.h. at 21 years. The plantation was grown from seed from Magdeburg, Germany, and the soil is a fox sandy loam on a well-drained site. A 32-year-old, unthinned Scots pine plantation in the same area averaged 19 cm (7.3 in.) in d.b.h. and 18.6 m (61 ft.) in height. This seed source was probably central Europe. A Scots pine plantation in northern New York averaged 26.0 m (85.5 ft.) tall and 48 cm (19 in.) d.b.h. at age 74–77 years. At 42 years the unthinned portion of the stand averaged 23 cm (9.2 in.) in d.b.h. (diameter at breast height) and contained a volume of 263.8 m³ ha⁻¹ (3768 ft.³/acre). Basal area was 36.0 m² ha⁻¹ (157 ft.²/acre). The area receiving five light thinnings at 5-year intervals to a basal area of 19.5–21.8 m² ha⁻¹ (85–95 ft.²/acre) had an average d.b.h. of 30 cm (11.8 in.) but volume was only 155.2 m³ ha⁻¹ (2217 ft.³/acre) and basal area was 25.7 m² ha⁻¹ (112 ft.²/acre). The heaviest thinning with five thinnings at 5-year intervals to a basal area of 14.9–17.2 m² ha⁻¹ (65–75 ft.²/acre) produced an average d.b.h. of 34 cm (13.3 in.) with 117.5 m³ ha⁻¹ (1679 ft.³/acre) of volume and 20.7 m² ha⁻¹ (90 ft.²/acre) of basal area. The bulk of the root system consists of horizontal roots close to the surface. The majority of these horizontal roots are within 20 cm (7.8 in.) of the surface. The horizontal root system is smaller on good soils than on poor soils. The depth of the horizontal root system is also related to soil moisture—it is deeper on the drier soils. On vigorous trees, the length of the longest horizontal roots ranged from 4.5 m (14.8 ft.) for 14-year-old trees to 17.1 m (56.0 ft.) for 52-year-old trees. Root systems on rocky soils are usually shorter than on sandy soils. The size of the stem and the length of horizontal roots are closely interdependent (York and Littlefield, 1942; Rudolph and Lemmien, 1959; Schreiner *et al.*, 1962; Steinbeck, 1966; Skilling and Nicholls, 1974; Skilling, 1981).

The regeneration cut is made to coincide with a heavy seed year. This can be predicted 1 year in advance because the cones take 2 years to mature. At the time of regeneration, the number of overstory trees is reduced to approximately 50/hectares (20/acre) by one or two fellings to provide the required light conditions for young seedlings and to reduce root competition for water and nutrients. The seed trees normally are felled when the reproduction is well established—usually within 5–10 years. Scots pine is an introduced

species that has been widely planted for the purpose of producing Christmas trees. It is an extremely hardy species which is adaptable to a wide variety of soils and sites. As a Christmas tree, it is known for its dark green foliage and stiff branches that are well suited for decorating with both light and heavy ornaments (York and Littlefield, 1942; Wright and Bull, 1963; Wright *et al.*, 1966a, b; Wright and Wilson, 1972; Skilling and Nicholls, 1974; Skilling, 1981). It has excellent needle retention characteristics and holds up well throughout harvest, shipping, and display. The needles of Scots pine are produced in bundles of two. They are variable in length, ranging from slightly over 2.54 cm (1 in.) for some varieties to nearly 7.62 cm (3 in.) for others. Color is likewise variable with bright green characteristic of a few varieties to dark green to bluish tones more prominent in others. The undersides of Scots pine needles are characterized by several prominent rows of white appearing stomatal openings. The bark of upper branches on larger, more mature trees displays a prominent reddish-orange color, which is very distinctive and attractive. Large amounts of cones are likewise produced that often persist on the tree from 1 year to the next. Like most pines two growing seasons are required to produce mature cones. On excellent sites within its native range mature trees may reach a trunk diameter of 76.2 cm (30 in.) or more and individual trees may exceed 37.5 m (125 ft.) in height (York and Littlefield, 1942; Wright and Bull, 1963; Wright *et al.*, 1966a, b; Wright and Wilson, 1972).

Scots pine is reproduced from seed. More than 35 different seed sources or varieties are commercially recognized. Seed is obtained by international collectors and marketed through reputable seed dealers. A few seed orchards have been established in the United States from which seed is locally collected. For Christmas tree production purposes seed is usually sown in the spring and the resulting seedlings are allowed to grow for 2 years in the nursery bed before they are lifted and sold to Christmas tree producers. There has been some research by university personnel to identify and produce genetically improved planting stock, although these efforts have not been totally successful (Laitakarai, 1927; Mosher and Wilson, 1977; Heit, 1969; Lemmien and Botti, 1974).

1.4.3 Monterey pine

Monterey pine has a very restricted distribution. It is native to just five areas: the Año Nuevo-Swanton area (San Mateo and Santa Cruz counties), the Monterey Peninsula and Carmel (Monterey county), Cambria (San Luis Obispo county), and Guadalupe and Cedros Islands off Baja California in Mexico. The species was more widely distributed at various times in the past. Fossil cones or needles of the Monterey pine have been recorded from 20 localities in California, including the famous La Brea Tar Pits. Most of the localities are near the coast and range from Tomales Bay in the north to Chula Vista near San Diego and on the Channel Islands (Vogl, 1973; Tjosvold and McCain, 1988; Toro and Gessel, 1999; Vogl *et al.*, 2002). The one inland locality is in Riverside county. The fossils range in age from middle Miocene through Pleistocene. The cones of this species are distinctive and one of the easiest to recognize from fossils. They are asymmetrical with large, smooth, bulbous umbos (knoblike protuberances) on the scales. The scales do not have sharp prickles like some pine species. Most of the Pleistocene cones are carbonized (also called coalified). Basically, the wood has turned into coal. In this process, the molecules that make up the cellulose begin to break down after prolonged burial. Hydrogen and oxygen atoms are released in the form of water, carbon dioxide, and methane gas. This leaves behind carbon—hence the term carbonized (Wheeler and Guries, 1982; Wheeler *et al.*, 1983, 1995; White, 1999).

The evolutionary history of the Monterey pine (*P. radiata*) and its close relative, the Bishop pine (*Pinus muricata*), first piqued the curiosity of paleontologists in the early 1900s. In the 1930s, Herbert Mason suggested that the disjunct populations of these pines could be explained by Tertiary-age islands. He hypothesized that the populations had been isolated on offshore islands millions of years ago, and that after these islands became part of the mainland, the pine's insular distribution persisted. It was a reasonable theory at the time, but geologic studies in recent decades have found no evidence for such islands, at least in central and northern California. In addition, later discoveries show that Monterey pine was much more widely distributed only a few tens or hundreds of thousands of years ago, well after

the end of the Tertiary Period. In a series of studies during the last half of the 1900s, pale botanist Daniel Axelrod used geologic, fossil, and associated floristic evidence to better piece together the evolutionary and geographic history of Monterey pine. According to Axelrod, the closed-cone pines originated in Central America from an ancestor related to the modern *Pinus oocarpa*. The closed-cone pines spread northward into California about 15 million years ago. By this time, *P. radiata* had already evolved into a distinct species. Monterey pine's widespread fossil distribution along the California coast led Axelrod to believe that it flourished throughout the Pleistocene. He theorized that it was not until a warm, dry period 4000–8000 years ago that it was driven to near extinction, surviving in the form of five small populations. He called this warm period the Xerotherm. Today it is more commonly referred to as the Climatic Optimum or early Holocene warm period (Whitlock *et al.*, 1993; Wikler and Gordon, 2000; Wikler *et al.*, 2000).

A few years ago, Connie Millar, a scientist with the United States Forest Service, developed a revised theory of the pine's history based on new fossil evidence and a refined understanding of climate change during the Pleistocene. Marine sediments and ice cores from the Atlantic, Pacific, and Arctic oceans have now given us high-resolution climate records going back hundreds of thousands of years. Pale temperatures have been determined from the shells of fossil organisms and from gases trapped in the ice, sometimes datable to individual years (Wilcox and Miller, 1975; Wilcox, 1983; Wilson, 1990; Wu *et al.*, 1998a). These scientific breakthroughs have enabled scientists to paint a much more detailed picture of climate change than was ever before possible. These records show that there have been at least 11 ice ages over the past million years. Each lasted for about 90 000 years. Between the glacial periods were warm interglacial periods of about 10 000 years, like the one we live in now. The Climatic Optimum (Axelrod's "Xerotherm"), when temperatures were even warmer than at present, appears to have had analogs in other interglacial periods. This casts doubt on Axelrod's theory, which relied on the premise that the early Holocene warming was unique. The previous interglacial period (125 000–111 000 years ago), for example, apparently had peak temperatures at

least two degree centigrade warmer than the period 8000–4000 years ago. Another important line of evidence has come from fossil pollen. Pollen is extremely durable and can last for millions of years (Zagory and Libby, 1985; Yang and Yeh, 1993; Wu *et al.*, 1998b, 1999). The tiny grains have distinctive morphologies and in many cases are identifiable to species. Fossil pollen samples collected from cores of lake, bog, and marine deposits can show what plants were living nearby and how the flora in a particular area changed over time with changes in climate (Old *et al.*, 1986; Owen, 1998; Ostrowska *et al.*, 1998).

For her study of Monterey pine, Millar drew upon pollen evidence from sediment cores in the Santa Barbara Channel. According to Millar, Monterey pine "was least abundant during full interglacials (i.e., the Holocene and previous interglacials), when oaks dominated coastal habitats, and was also uncommon during the cold periods of the glacials, when junipers dominated. Monterey pine, as well as other coastal pines, increased dramatically in abundance and shifted in coastal location during climate periods intermediate between these extremes—i.e., at times such as the end of the ice ages (climate warming), during 'interstadial periods' (warmish intervals within the ice ages), and at the end of interglacials (climate cooling)." She also found that, "Times of abundance of Monterey pine correlated also with increases in charcoal abundances in the sediment cores, corroborating that fire plays an important role in dispersal and spread of Monterey Pines by opening cones and preparing seed beds (Pawsey, 1964; Pederick, 1967; Reyes and Casal, 2001; Rogers, 2004)."

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

1.5.1 Loblolly pine

Although Loblolly pine falls prey to many insect pests, including southern pine beetle, pine engraver beetle, pine tip moths, and seedling debarking weevils, it also provides rich habitat for animals and other plant species. Forests and stands of trees provide excellent habitat for wildlife, including white-tailed deer, gray squirrels, rabbits, and birds such as wild turkey and bobwhite quail. Warblers

and nuthatches thrive in Loblolly pine forests, and old-growth areas sustain other species such as the red-cockaded woodpecker. In the Bay region the trees provide important nesting habitat for bald eagles and osprey. In areas that are subject to severe erosion along the Bay and tidal tributaries, loblolly pines are frequently used for soil stabilization in areas that are subject to severe erosion (Echt *et al.*, 1998).

In several areas on the Assateague refuge, you will note that the loblolly pines have been cut down and burned. Unfortunately, a southern pine beetle infestation hit the refuge in 1994, and the dead trees have had to be destroyed. New pines are growing naturally, and in many of the devastated areas, oaks and other hardwoods have been planted.

1.5.2 Scots pine

Scots pine in North America is subject to a number of agents that can severely damage or kill the trees. Some of these agents are not present in Europe and Asia and, as a result, the species has not yet had an opportunity to develop genetic resistance. Fire and wind can damage the trees (Dickson and Winch, 1970; Genys, 1976; Dorworth, 1977). Young stands have thin bark and are heavily damaged by fire. Older trees with thicker bark are moderately resistant. Scots pine has more branches per whorl than red or white pine and this large number of branches make the tree weak at the nodes. During severe wind storms, trees may snap off at the nodes 3–6 m (10–20 ft.) above the ground. Wildlife and insects are also damaging. The pine grosbeak feeds on the terminal and lateral buds of Scots pine causing numerous small crooks. Trees of Scandinavian provenances are heavily attacked. In Christmas tree plantations, this feeding can cause major economic losses; a single year's feeding can reduce the tree harvest by 50%. This is a minor problem to timber growers, however (Dickson and Winch, 1970; Genys, 1976; Dorworth, 1977). On occasion, porcupine seriously damage Scots pine plantations by girdling young trees, causing dead tops.

The pine root collar weevil (*Hylobius radialis*) is a major cause of tree death in young plantations in the Lake States. The weevil girdles the tree at the base, killing it within 3 to 4 years. The damage is especially severe on dry sandy soils. The fast-

growing central European trees are particularly susceptible (Laitakarai, 1927; Mosher and Wilson, 1977; Heit, 1969; Lemmien and Botti, 1974). In Michigan, on low quality sites, mortality frequently reaches 70–80%. The pine root tip weevil (*Hylobius rhizophagus*) causes serious damage in Michigan on Scots pine Christmas trees grown from stump culture. These trees result from leaving the lower limbs on cut trees to grow into a second tree crop. The pine root tip weevil larvae feed on the roots and root tips, resulting in reduced height growth and flagged shoots, and eventual death. In some cases, the pine root tip weevil and the pine root collar weevil attack some Scots pine stands simultaneously, causing more mortality than expected from either insect alone (Laitakarai, 1927; Mosher and Wilson, 1977; Heit, 1969; Lemmien and Botti, 1974). The European pine sawfly (*N. sertifer*) causes moderate damage in Christmas trees and ornamental plantings. Heavy defoliation reduces growth from 10% to 20%. The fast-growing Scots pine variety *uralensis* shows some resistance to this insect while the slow-growing variety *iberica* is most susceptible (Laitakarai, 1927; Mosher and Wilson, 1977; Heit, 1969; Lemmien and Botti, 1974).

If Scots pine is pruned in midsummer, the Zimmerman pine moth may be attracted to the fresh pitch. The larvae feed in the cambial region, causing masses of coagulated pitch and frass to collect. Feeding by several larvae at the same whorl may kill the tree top or the entire tree. Partially girdled stems frequently break at the weakened area during storms (Paul, 1916; Read, 1971; Nicholls and Skilling, 1974; Ruby and Wright, 1976; Wright *et al.*, 1976). The white pine weevil (*Pissodes strobi*) burrows into terminal shoots and kills them. This insect is very damaging to trees on light soils but causes only minor damage on better sites. The eastern pine shoot borer (*Eucosma gloriola*) also burrows in the pith of new growth. In Michigan plantations, this insect is universal but causes only minor damage. The pine spittlebug (*Aphrophora parallela*) is a serious pest in many Scots pine Christmas tree plantations (Paul, 1916; Read, 1971; Nicholls and Skilling, 1974; Ruby and Wright, 1976; Wright *et al.*, 1976). Heavy infestations of spittlebugs may cause twig, branch, and tree mortality. In one 19-year-old Scots pine plantation in southern Michigan, the pine spittlebug has apparently acted

as the vector for the fungus disease *Sphaeropsis sapinea*; mortality is now 25% and is continuing. *Lophodermium* needlecast caused by the fungus *Lophodermium seditiosum* is the most serious disease of Scots pine Christmas tree plantations. The major loss is due to premature defoliation resulting in unsalable Christmas trees. In general, the longer needle provenances are resistant to this disease. The problem is minor in forest stands (Paul, 1916; Read, 1971; Nicholls and Skilling, 1974; Ruby and Wright, 1976; Wright *et al.*, 1976).

Scots pine is also a host for brown spot needle disease of southern pines (*Scirrhia acicola*). This disease, like *Lophodermium*, causes premature defoliation and is primarily limited to Christmas tree plantations. The long needle provenances are also more resistant to this disease (Rudolph and Lemmien, 1959; Schreiner *et al.*, 1962; Steinbeck, 1966; Skilling and Nicholls, 1974; Skilling, 1981). Western gall rust (*Endocronartium harknessii*) is common on Scots pine in the Lake States and the Northeast. Individual trees may have several hundred galls. In most cases damage is limited to branch mortality and growth loss. As described earlier, Scots pine is susceptible to scleroderris canker. This disease is present in many areas in Europe, and as a result, certain Scots pine provenances show some resistance. Scots pine is more resistant to scleroderris canker than red pine, and in some areas, red pines have been eliminated from the stand while Scots pines are still alive. Scleroderris canker can be spread on cut Scots pine Christmas trees. Therefore, state quarantines have been established to prevent the movement of this disease into noninfected areas (Rudolph and Lemmien, 1959; Schreiner *et al.*, 1962; Steinbeck, 1966; Skilling and Nicholls, 1974; Skilling, 1981). When southern seed sources of Scots pine are planted too far north of their normal range, severe foliage winter injury develops. This winter injury causes both branch and tree mortality. In the Lake States, a large number of Christmas tree plantations have been destroyed by this problem. Many of these problems in Scots pine plantations are the result of planting this species on very poor sites or planting the wrong seed source (York and Littlefield, 1942; Wright and Bull, 1963; Wright *et al.*, 1966a, b; Wright and Wilson, 1972). Scots pine has the inherent ability to produce excellent, straight-boled stands under the proper conditions. Hundreds of Scots pine plantations throughout

the Lake States and the Northeast are equal to or better than the best red pine stands. When Scots pine is planted on very poor sites, however, or when improper seed sources are used, damage by insects is so severe as to make the final stand useless for timber production (York and Littlefield, 1942; Wright and Bull, 1963; Wright *et al.*, 1966a, b; Wright and Wilson, 1972).

1.5.3 Monterey pine

Monterey pine is the most common pine in the southern hemisphere, where no pines are native (except that *Pinus merkusii* barely crosses the line in Sumatra). The three remaining native stands of var. *radiata* are infected and under threat of extinction from pitch canker, a fungal disease native to the southeast United States and found (in 1986) to have been introduced to California. When trees begin to die of the disease, they attract bark beetles that provide a pathway for infection of other trees. In some stands, 80–90% of trees are infected. If the disease is introduced in agroforestry areas dependent upon *radiata* pine, such as New Zealand, it could have catastrophic effects in those countries as well (Furnier and Adams, 1986; Eldridge, 1996). Its cones are serotinous, i.e., they remain closed until opened by the heat of a forest fire; the abundant seeds are then discharged to regenerate the burned forest. The cones may also burst open in hot weather (Hood and Libby, 1980; Hong *et al.*, 1993; Gascon *et al.*, 2000).

There is no evidence that Monterey pine was ever continuously distributed along the California coast at any one time over the past two million years. Instead, its populations were always fragmented. The species expanded, shifted, or colonized new sites during periods of favorable climate. Its range contracted and some forest stands died out during periods of unfavorable climate. Many biologists are concerned about the survival of the five native stands of Monterey pine (Kinloch, 1992; Jorgensen and Hamrick, 1997; Jacobs *et al.*, 2000). On Guadalupe Island, for example, the population has long been threatened by goats. In 1964 only 320 trees remained. By 1992 the population had dwindled to 150. On the mainland, urbanization, fire suppression, genetic contamination, and pine pitch canker (a deadly fungal disease ravaging many stands) all threaten

the trees (Jones *et al.*, 1996; Johnson *et al.*, 1997; Jayawickrama and Carson, 2000). Domesticated Monterey pines are common in the United States as garden trees, and small ones are used for Christmas trees. Although the species is not likely to become extinct, it is important that the wild populations be preserved. In other parts of the world, domesticated Monterey pines are a major forest tree. In fact, it is the world's most planted conifer. Over 10 million acres have been planted. There are 2 million acres in Australia, 3 million in New Zealand, and millions more in Chile, Uruguay, Argentina, Spain, South Africa, and Kenya. Selective breeding has produced fast-growing trees with straight trunks—ideal for the forest industry (Nicholls and Eldridge, 1980; Ohmart and Voight, 1981; Nowak and McBride, 1991). Most of these countries have active breeding programs to develop still better strains for lumber and paper manufacturing. DNA studies have shown that the material from which these foreign plantings were developed was not very diverse genetically. On the contrary, the native forests are genetically diverse. According to Millar, the diverse germplasm in these native populations have “inestimable value”. It could, for example, help with the development of strains that are more resistant to certain insect pests and diseases (Lill, 1976; Krupkin *et al.*, 1996; Lavery and Mead, 1998).

Given the Pleistocene history of the species, Millar recommends expanding conservation efforts beyond the five native populations. For example, “neo-native” forests could be planted in areas where the pine lived only a few thousand years ago such as near Point Reyes, Point Sur, Santa Barbara, and San Diego. This would help ensure survival of genetically diverse forests (Lindsay, 1932; Matheson, 1980; McDonald and Laacke, 1990; Matziris, 1995). When Dr. Millar spoke to the Monterey Bay Paleontological Society a few years ago, she told the tragic story of a park along the northern California coast where all the Monterey pines were cut down. The trees were perfectly healthy, but were removed because they were a “non-native” species. Yet, a few thousand years ago the trees might have grown there naturally. One of the great values of fossils is that they enable us to see the present from the perspective of geologic time (Murphy, 1981; Moran and Bell, 1987; Moran *et al.*, 1988;

Mouradov *et al.*, 1999a). As Monterey pine clearly shows, this perspective can give us a greater appreciation for the present and help us plan better for the future. When one visits the Monterey Peninsula or drives by the trees along Highway 1 near Año Nuevo State Reserve, it is easy to see their remarkable cones, and consider their clever survival strategy. They are not relicts of the Ice Age on the verge of dying out, but instead are trees lying in wait for the next shift toward a cooler climate (Mouradov *et al.*, 1999b; Mouradov and Teasdale, 1999; Mathews and Campbell, 2000).

2. DEVELOPMENT OF TRANSGENIC PINES

Genetic modification of conifers through gene transfer technology is now an important field in forest biotechnology. Particle bombardment and *Agrobacterium*-mediated transformation have been used on gene transfer in conifers. The use of particle bombardment has produced stable transgenic plants in *Picea abies*, *Picea glauca*, *Picea mariana*, and *P. radiata*. Transgenic plants have been produced from *Larix decidua*, *P. abies*, *P. glauca*, *P. mariana*, *Pinus strobus*, *P. taeda*, and *P. radiata* via *Agrobacterium*-mediated transformation. *Agrobacterium*-mediated transformation has advantages over particle bombardment such as a simpler integration pattern and a limited rearrangement in the introduced DNA. At present, genetic transformation of conifers has been directed toward improving growth rate, wood properties and quality, pest resistance, stress tolerance, and herbicide resistance. All of these could drive forestry to enter a new era of productivity and quality.

2.1 Donor Genes: Source, Isolation, and Cloning, and Designing Transgenes

Since the first transgenic tree was obtained in 1987 (Fillatti *et al.*, 1987), stable transformation has been developed for many forest tree species and used to transfer economically important genes conferring traits such as virus, insect, and herbicide resistance (Birch, 1997; Herschbach and Kopriva, 2002). However, transgenic conifers were only reported 10 years ago (Huang *et al.*, 1991) and are restricted to a very few species (Ellis *et al.*,

1989, 1991; Charest *et al.*, 1991, 1993, 1996; Walter *et al.*, 1994, 1998, 1999, 2002, 2004; Levee *et al.*, 1997, 1999; Wenck *et al.*, 1999; Klimaszewska *et al.*, 1997, 2001; Le *et al.*, 2001; Tang, 2001; Tang *et al.*, 2001; Gould *et al.*, 2002). Genetic transformation using *Agrobacterium* is the most efficient procedure for introducing DNA into the genome of many plant species (Smith and Hood, 1995). Several infectious *Agrobacterium* strains that resulted in tumor development in numerous coniferous species have been identified since 1986 (Sederoff *et al.*, 1986; Morris *et al.*, 1989; Stomp *et al.*, 1990, 1991). However, there are only a few reports of the regeneration of stably transformed conifers using *Agrobacterium* (Huang *et al.*, 1991; Levee *et al.*, 1997, 1999; Wenck *et al.*, 1999; Newton *et al.*, 2001; Tang *et al.*, 2001; Gould *et al.*, 2002). Only a few stable transformants have been obtained biolistically (Charest *et al.*, 1996; Walter *et al.*, 1998, 1999; Clapham *et al.*, 2000). Recent progress made in somatic embryogenesis in conifers provides opportunities to produce transgenic plants in a number of species that will lead to their application in forest industry (Sutton, 2002; Tang and Newton, 2003, 2004; Tang *et al.*, 2004, 2005, 2006).

With the various gene transfer methods currently available, simple placement or transfer of DNA into a plant cell is no longer a limiting factor (Birch, 1997). However, both the mechanism for DNA transfer to a plant cell and targeting of the DNA to a complex tissue or organ competent for regeneration is still a major limitation (Herschbach and Kopriva, 2002). Since the aim is usually to produce transgenic trees with better wood properties, which can only be evaluated in the adult tree, there exists a long lag time between the actual accomplishment of transformation and the evaluation of its success or failure (Merkle and Dean, 2000; Pena and Sequin, 2001; Herschbach and Kopriva, 2002).

There are many genes available for use in conifer transformation experiments. However, most of those that have been used are reporter genes establishing a model transformation system, and very few have been used for novel phenotypes or for tolerance to various stresses (Walter *et al.*, 2002). Transgenic plants in the field of forest biotechnology has been subjected to several reviews (Tzfira *et al.*, 1996, 1998; Merkle and Dean, 2000; Pena and Sequin, 2001; Van Raemdonck

et al., 2001; Herschbach and Kopriva, 2002; Walter *et al.*, 2002; Tzfira and Citovsky, 2002). In this chapter, we provide an overview of the current state of knowledge on genetic transformation in conifers, and their applications in future tree improvement and forest production.

2.2 Methods Employed

2.2.1 *Agrobacterium*-mediated transformation in conifers

The molecular mechanism of Ti-plasmid transfer, integration, and expression has been a key research area in plant genetic engineering (Koncz and Schell, 1986; Tzfira and Citovsky, 2002). Research related to these areas includes molecular and genetic analyses of the transfer DNA (T-DNA) transfer machinery in *Agrobacterium tumefaciens*, regulation of the *vir* genes of *A. tumefaciens* that direct this transfer, and a molecular analysis of the form of T-DNA that is transferred (Tzfira and Citovsky, 2002). The integration pattern for foreign genes introduced into plant cells via *Agrobacterium*-mediated transformation is, in general, strikingly different from the pattern resulting from particle bombardment (Hoekema *et al.*, 1983; Stachel *et al.*, 1985; Sheikholeslam and Weeks, 1987; Godwin *et al.*, 1991; Hood *et al.*, 1993). The process of foreign gene transfer from *Agrobacterium* into plant cells includes several essential steps: (1) bacterial colonization, (2) induction of the bacterial virulence system, (3) T-DNA processing, (4) bacterial attachment, (5) generation of the T-DNA transfer complex, (6) T-DNA transfer and nuclear targeting, and (7) integration of T-DNA into the plant genome (Sheng and Citovsky, 1996).

Crown gall is a neoplastic disease caused by the infection of dicotyledonous plants by virulent strains of the gram-negative soil bacterium, *A. tumefaciens* (Birch, 1997). During the infection process, part of a bacterial plasmid, called the tumor inducing (Ti) plasmid, is transferred from the bacterium to the plant, where it stably integrates into the nuclear DNA (Tzfira and Citovsky, 2002). This process is the only known natural occurrence of DNA transfer between kingdoms (Sheng and Citovsky, 1996; Birch, 1997). Bacterial DNA transferred to the plant not only

induces the formation of a tumor, but also contains information that directs the plant cell to produce and secrete compounds that the *Agrobacterium* can utilize as a source of carbon and nitrogen (Sederoff *et al.*, 1986; Diner and Karnosky, 1987; Sheng and Citovsky, 1996; Dillen *et al.*, 1997).

The process begins when a plant is wounded. A wounding event, which often occurs at the base of the stem of the plant, causes the plant to release compounds that attract *Agrobacterium* to the damaged cells (Citovsky *et al.*, 1989). When *Agrobacterium* reaches the plant, it attaches to a receptor on the surface of the plant cell and begins to synthesize cellulose, resulting in a strong connection between the two cells (Sheng and Citovsky, 1996). Subsequently, phenolic compounds secreted by the plant are recognized by a protein kinase on the surface of the bacteria (a kinase is an enzyme that phosphorylates specific target proteins and sometimes itself). In this case, the kinase (VirA, where “vir” is for virulence) autophosphorylates in response to the phenolics and then transfers the phosphate to another protein (VirG) within the bacterium (Tzfira and Citovsky, 2002). In its phosphorylated state, VirG is able to induce transcription of genes on the Ti plasmid (Citovsky *et al.*, 1989; Rossi *et al.*, 1996).

The Ti plasmid encodes for proteins that function in the DNA transfer process in addition to containing the actual DNA that is transferred to the plant (Tzfira and Citovsky, 2002). An endonuclease specifically cleaves the Ti plasmid, which results in the release of a piece of single-stranded T-DNA of approximately 20 kb (Sheng and Citovsky, 1996). The T-DNA remains single stranded and is coated with proteins that serve both to protect the DNA and target it to the plant cell nucleus by virtue of nuclear localization signals found within the proteins (Tzfira and Citovsky, 2002). Once inside the plant nucleus, the T-DNA may integrate into the plant chromosome. The integrated T-DNA gene products direct the plant to synthesize auxins and cytokinins that cause plant cells to grow in an unregulated manner resulting in tumor formation (Hansen *et al.*, 1994). Additionally, the T-DNA causes the plant to synthesize opines that the bacteria can use as a carbon and nitrogen source (Hansen *et al.*, 1994; Sheng and Citovsky, 1996).

Agrobacterium-mediated or direct transformation methods have been used for more than 120 species of at least 35 families, including the major economic crops, vegetables, ornamental, medical, and fruit trees, and pasture plants (Birch, 1997). Furthermore, efficient methodologies of *Agrobacterium*-mediated gene transfer have been established mainly for dicotyledonous plants. However, *Agrobacterium*-mediated gene transfer has been applied to about 25 coniferous species from the genera *Abies*, *Larix*, *Libocedrus*, *Picea*, *Pinus*, *Pseudotsuga*, and *Tsuga* (Table 2). Reporter genes and important trait genes have been tested in conifers by *Agrobacterium*-mediated transformation. The procedure of *Agrobacterium*-mediated genetic transformation (Figure 1) is widely used in conifers. These studies demonstrated that several factors are important for the application of *Agrobacterium*-mediated gene transfer in conifers and other plants (Tang and Newton, 2003, 2004; Tang *et al.*, 2004, 2005, 2006).

2.2.2 Transformation via particle bombardment

The ability to deliver foreign DNA directly into regenerated cells, tissues, and organs appears to provide the best method for achieving truly genotype-independent transformation bypassing *Agrobacterium* host specificity and tissue culture-related regeneration difficulty (Birch, 1997). There is no biological limitation to the actual DNA delivery process, so genotypic specificity is not a limiting factor (Birch, 1997). Recent advances in the transformation of crop plants with particle bombardment have demonstrated that DNA can be inserted into virtually any tissue and cell that is impacted by the particle (Bommineni *et al.*, 1993). Indeed, foreign genes were expressed in all conifer tissues that have been tested thus far by exposure to particle bombardment, including embryos, seedlings, megagametophytes, xylem, pollen, needles, buds, cell suspension cultures, embryogenic callus, cell aggregate cultures, and roots (Table 3). While almost all of this expression was transient, it yielded valuable information on factors involved in the expression of introduced genes in the various tissues competent for regeneration (Tang and Newton, 2003, 2004; Tang *et al.*, 2004, 2005, 2006).

^(a) *A.t.*, *Agrobacterium tumefaciens*; *A.r.*, *Agrobacterium rhizogenes*

Parameters that were found to influence successful particle and DNA delivery into regenerable tissue of plants included the condition of the explant prior to bombardment, environmental factors (including temperature and humidity), and influences of the parameters affecting transient activity of the marker genes (Birch, 1997). Additional important parameters also included depth of particle penetration and degree of tissue damage as a function of accelerating force and timing of selection. In *Pinus*, transient expression of the green fluorescent protein (*GFP*) gene in embryogenic masses of *P. strobus* via

particle bombardment has been achieved (Tian *et al.*, 1997). Transient expression of *uidA* (β -glucuronidase, Jefferson *et al.*, 1987) in cotyledon cells of *P. taeda* by particle bombardment has been reported (Stomp *et al.*, 1991), and these results demonstrated that microprojectile bombardment had potential for the production of transgenic plants in pine (Table 3). Transient regenerated pine has been obtained by transforming embryogenic tissues of *P. radiata* using particle bombardment (Figure 2) (Walter *et al.*, 1994, 1998), and more than 150 transgenic *P. radiata* plants were produced with 20 independent transformation

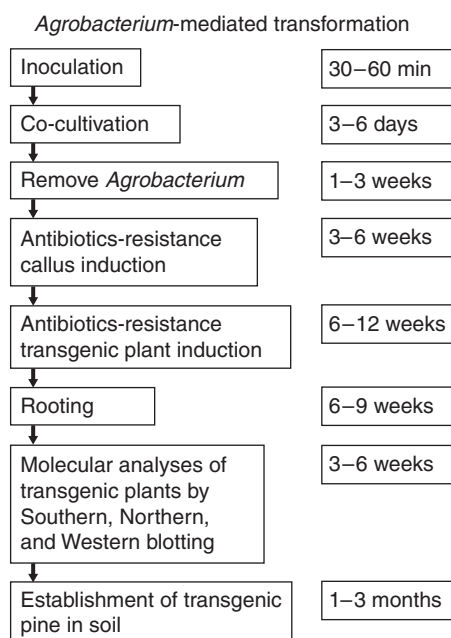

Figure 1 Procedure of *Agrobacterium*-mediated transformation

expression events with four different embryogenic clones (Walter *et al.*, 1998).

2.2.3 Transformation using electroporation

Transformation using electroporation as a method of direct gene transfer has potential for genetic improvement and for studies of gene structure and function in forest trees. This is especially attractive when used in conjunction with protoplasts that are capable of regeneration to somatic embryos or

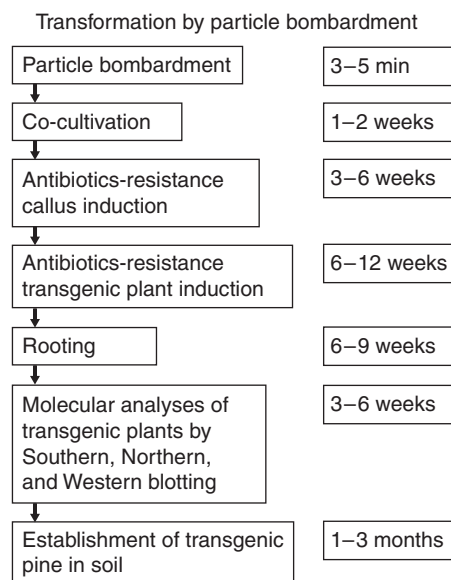

Figure 2 Procedure of transformation via particle bombardment

plantlets (Bekkaoui *et al.*, 1988, 1990; Tautorius *et al.*, 1989; Wilson *et al.*, 1989). Because electroporation avoids the host-range limitation of *Agrobacterium*-mediated transfer methods, it has the further advantage of being useful for the rapid evaluation of the functionality of plasmid construction, and for assessing transient gene expression, and stable transformation. Electroporation has been utilized to transfer genes into protoplasts isolated from embryogenic cell cultures of *P. glauca* (Bekkaoui *et al.*, 1988), *P. mariana* (Tautorius *et al.*, 1989), *P. taeda* (Gupta *et al.*, 1988), and *Larix × eurolepis* (Charest *et al.*, 1991), and from nonembryogenic

Figure 3 GFP transgenic pine calli derived from *Agrobacterium*-mediated transformation

cultures of *P. radiata* (Campbell *et al.*, 1992) and *Pinus banksiana* (Tautorus *et al.*, 1989). These experiments have demonstrated that 35S promoter (35S) of cauliflower mosaic virus (CaMV) and the nopaline synthase promoter function in conifer tissues.

The commonly used reporter genes, such as the firefly luciferase (*luc*) gene, GFP (Figure 3), and *uidA* (*GUS*) gene, can be used to assess gene activity in conifer protoplasts. Bekkaoui *et al.* (1990) reported that the level of foreign gene activity in electroporated *P. glauca*, *P. mariana*, and *P. banksiana* protoplasts is dependent on the promoter transferred, electroporation conditions, as well as on the target cell line under investigation. Gupta *et al.* (1988) reported that protoplast viability was reduced from 90% to 45–55% after electroporation. However, the transient expression of the *luc* gene was detected in protoplasts surviving 36 h after electroporation. Gene expression was improved by the addition of polyethylene glycol to the electroporation mixture. According to Tautorus *et al.* (1989), transient expression of the chloramphenicol acetyltransferase gene (*CAT*) in electroporated *P. mariana* and *P. banksiana* protoplasts was affected by the cell lines used, by voltage, temperature, and by the plasmid concentration and conformation. Increasing the plasmid DNA concentration resulted in higher

levels of transient *CAT* expression. A linearized plasmid gave 2.5 times higher levels of *CAT* enzyme activity than did circular plasmid in *P. banksiana*. A heat shock treatment of protoplasts for 5 min at 45 °C resulted in enhanced *CAT* gene expression for *P. mariana* and *P. banksiana*. Because of the difficulty in plant regeneration from conifer protoplasts, transformation using electroporation is mainly used to study transient expression of genes and factors influencing transgene expression (Tang and Newton, 2003, 2004; Tang *et al.*, 2004, 2005, 2006).

2.3 Selection of Transformed Tissue

Three antibiotics carbenicillin, claforan, and timentin are usually used to eliminate *A. tumefaciens* during the genetic transformation of pine. *A. tumefaciens* strains, EHA105, GV3101, and LBA 4404, all harboring the plasmid pCambia1301, which carries the selectable marker gene, hygromycin phosphotransferase (*hpt*) controlled by the CaMV 35S promoter and terminator, and the *uidA* reporter gene (*GUS*) driven by the CaMV 35S promoter and the terminator of nopaline synthase gene, have been tested. Exposure to 350 mg l⁻¹ carbenicillin, claforan, and timentin, respectively for up to

6 weeks did not eliminate the *Agrobacterium*, while antibiotics at 500 mg l⁻¹ eradicated them from the co-cultivated zygotic embryos. All three antibiotics increased callus growth and shoot regeneration at 350 and 500 mg l⁻¹ each, but reduced callus growth and shoot regeneration at 650 mg l⁻¹ when compared with controls. Putative transgenic calli were selected for continued proliferation and differentiation on 4.5 mg l⁻¹ hygromycin-containing medium. Transformed calli and transgenic plants produced on a selection medium containing 4.5 mg l⁻¹ hygromycin were confirmed by GUS histochemical assays, by polymerase chain reaction (PCR), and by Southern blot analysis. These results are useful for future studies on optimizing genetic transformation procedures in pine (Tang and Newton, 2003, 2004; Tang *et al.*, 2004, 2005, 2006).

Growth and differentiation of transgenic calli of pine were reduced by high concentrations of antibiotics (carbenicillin, claforan, and timentin, 650 mg l⁻¹ each), although it was observed that lower concentration (350 and 500 mg l⁻¹ carbenicillin, claforan, and timentin) caused an increase. These results indicate that the establishment of an efficient *A. tumefaciens*-mediated transformation protocol for stable integration of foreign genes into pine was also dependent on the selection of antibiotics. This could be useful for future studies on growth and differentiation of transformed cells as well as transferring reporter and/or functional genes to pine and other conifers (Tang and Newton, 2003, 2004; Tang *et al.*, 2004, 2005, 2006).

2.4 Regeneration of Whole Plants

Since the first report of conifer transformation by Huang *et al.* (1991), significant advances have been made with *Agrobacterium*-mediated genetic transformation. In the last decade, successful transformation has been accomplished with *Larix*, *Picea*, and *Pinus*, although the transformation efficiency varies between species. Transgenic regenerated plantlets were obtained with *L. decidua*, *Pinus halepensis*, and *Pseudotsuga menziesii* (Dandekar *et al.*, 1987; Huang *et al.*, 1991; Tzfira *et al.*, 1996) infected by *Agrobacterium rhizogenes*, and embryogenic tissue of hybrid larch was transformed by *A. tumefaciens* (Levee *et al.*, 1997). According to Levee *et al.*

(1997), 1–2 transformation events per 100 co-cultivated embryogenic tissues were obtained with hybrid larch using *A. tumefaciens*. The addition of 100 µM coniferyl alcohol during the co-cultivation step increased the transformation frequency of kanamycin-resistant tissues where other substances known to be virulence inducers, such as acetosyringone and syringaldehyde, did not seem to have any effect (Levee *et al.*, 1997). Different bacterial strains (C58, pMB90, EHA101, and LBA4404) with various chromosomal backgrounds were tested, but none of them increased significantly the frequency of kanamycin-resistant tissues (Levee *et al.*, 1997). Tzfira *et al.* (1996) used *A. rhizogenes* strain LBA9402 to transform *P. halepensis* embryos, seedlings, and shoots. Mature embryos exhibited susceptibility to the *Agrobacterium* with more than 85% showing considerable transient β-glucuronidase (GUS) expression in the radicle. GUS expression was also observed in cotyledons, but at a lower rate in about 24% of the embryos (1–5 spots/embryo) (Tang and Newton, 2003, 2004; Tang *et al.*, 2004, 2005, 2006).

Agrobacterium-mediated gene transfer is widely used in plant biotechnology laboratories; however, large-scale use of this organism in conifer transformation has been limited due to difficult propagation of explant material, selection inefficiencies and low transformation frequency (Wenck *et al.*, 1999). Wenck *et al.* (1999) have investigated co-cultivation conditions and different disarmed strains of *Agrobacterium* to improve transformation. They found that extra virulence genes including either a constitutively active *virG* or extra copies of *virG* and *virB*, both from pTiBo542, increased transformation efficiencies of Norway spruce 1000-fold from initial experiments where little or no transient expression was detected (Wenck *et al.*, 1999). In Loblolly pine, transient expression was increased 10-fold utilizing modified *Agrobacterium* strains (Wenck *et al.*, 1999). *Agrobacterium*-mediated gene transfer is a useful technique for large-scale generation of transgenic Norway spruce and may prove useful for other conifer species (Wenck *et al.*, 1999). During the same year, a genetic transformation procedure for white pine was developed after co-cultivation of embryogenic tissues with *A. tumefaciens* (Levee *et al.*, 1999). This efficient transformation procedure led to an average of four independently transformed lines

Figure 4 Transgenic pine established in soil

per gram of co-cultivated embryogenic tissue, and up to 50 transformed lines were obtained in a routine experiment (Levee *et al.*, 1999). Constructs bearing the *uidA* gene or the *GFP* gene were introduced and GUS or GFP activity was followed over time. The expression of the *uidA* gene was lowest with a 35S-*gus*-intron construct and was 20-fold higher with a 35S-35S-*AMVgus::nptII* construct. The addition of scaffold attachment region sequences surrounding the *gus::nptII* fusion did not significantly enhance the GUS activity (Le *et al.*, 2001). Transformed mature somatic embryos have been germinated

and plantlets have been acclimatized (Levee *et al.*, 1999).

Both family and species types are important for the application of *Agrobacterium*-mediated gene transfer in conifers (Figure 4). Embryos of 24 open-pollinated families of Loblolly pine (*P. taeda*) were used as explants to conduct *in vitro* regeneration (Tang *et al.*, 1998; Tang and Ouyang, 1999; Tang, 2000). *A. tumefaciens* strain, GV3101 harboring the plasmid pPCV6NFHygGUSINT, was used to transform mature zygotic embryos of seven families of Loblolly pine. The frequency of transformation varied among families. The highest

frequency (100%) of transient GUS-expressing embryos was obtained from family 11-1029 with over 300 blue spots per embryo. Ninety transgenic plants were regenerated from hygromycin-resistant calli derived from families WO3, 8-1082 and 11-1029, and 19 transgenic plantlets were established in soil. The presence of the *uidA* gene in the plant genome was confirmed by PCR, Southern blot, and plant DNA/T-DNA junction analysis (Park *et al.*, 2000; Tang, 2001; Tang *et al.*, 2001).

In *Picea*, transgenic plants of three species were produced after co-culture of embryogenic tissue with the disarmed strain of *A. tumefaciens* C58/pMP90/pBIV10 and selection on medium containing kanamycin (Klimaszewska *et al.*, 2001). Transformation frequencies were dependent on the species, genotype, and post-co-cultivation procedure. Of the three species tested, *P. mariana* was transformed at the highest frequency, followed by *P. glauca* and *P. abies*. The transgenic state of the embryogenic tissue was initially confirmed by histochemical GUS assay followed by southern hybridization. Transgenic plants were regenerated for all three species (Klimaszewska *et al.*, 2001). At the same time, Le *et al.* (2001) developed an efficient and reproducible procedure for the transformation of white spruce, *P. glauca* (Moench) Voss, embryogenic tissues by using *A. tumefaciens*-mediated gene transfer. They co-cultivated rapidly dividing white spruce embryogenic tissues with disarmed *A. tumefaciens* strains containing additional copies of the virulence regions from plasmid pToK47. The highest frequency of transformation was obtained with 5-day-old tissues grown in liquid medium and co-cultivated with *Agrobacterium* for 2 days in the medium containing 50 μ M acetosyringone. Transgenic plants were regenerated from transformed tissues within 4 months of co-culture (Le *et al.*, 2001).

Recently, a shoot-based and genotype-independent Loblolly pine (*P. taeda*) transformation method was established by *A. tumefaciens* mediated-gene transfer (Gould *et al.*, 2002). Shoots from seedlings aged 4–6 weeks and adventitious shoots from culture were inoculated with *A. tumefaciens* EHA101 (pGUS3), or EHA105 (pSSLa.3), subjected to selection and regenerated. The overall recovery of *P. taeda* shoots was 10–20%, while recovery of intact rooted plants was about 1% due to difficulty in rooting. The addition

of a shoot multiplication step and effective rooting protocols will improve the efficiency of this genotype-independent transformation method in *P. taeda* (Gould *et al.*, 2002). In *P. radiata*, Charity *et al.* (2002) demonstrated that an *A. tumefaciens*-mediated transformation protocol was developed for detached cotyledons of zygotic embryos resulting in up to 55% of the cotyledons transiently expressing the reporter gene *uidA*. Transient expression of *uidA* was improved when detached cotyledons were precultured on half-strength medium containing cytokinin for 7 days, wounded by vortexing and then vacuum infiltrated in a solution of *A. tumefaciens* (Charity *et al.*, 2002).

Particle bombardment-mediated transformation can be used to regenerate whole plants (Ellis *et al.*, 1991; Charest *et al.*, 1993; Walter *et al.*, 1994). The expression of foreign genes in conifers was observed on meristematic cells that have the ability to rapidly divide and have a high rate of metabolic activity. Cells with high metabolic activity are most likely to be active in endogenous gene expression with all the functions for gene transcription and translation actively expressed. Therefore, genes introduced into these cells would also have a higher probability of being expressed, since: (1) DNA replication may aid in the incorporation of foreign DNA, and (2) a certain phase (S phase) in the cell cycle may be a prerequisite for DNA integration into the genome. Transformation of conifers by particle bombardment included *Larix laricina* (Klimaszewska *et al.*, 1997), *L. decidua* (Duchesne *et al.*, 1993), *P. abies* (Robertson *et al.*, 1992), *P. glauca*, *P. mariana* (Duchesne and Charest, 1991; Charest *et al.*, 1996), *P. radiata* (Walter *et al.*, 1998), *P. strobus* (Tian *et al.*, 1997), *P. taeda* (Stomp *et al.*, 1991), and *P. menziesii* (Goldfarb *et al.*, 1991).

Stable transformation of *P. glauca* by particle bombardment and transgenic regenerated plantlets were obtained by transforming embryogenic cultures (Ellis *et al.*, 1991). Incorporation of the introduced genes into the genome was confirmed by PCR and Southern blot analysis of embryogenic callus and regenerated transformed plants, as well as spruce budworm feeding trials with transformed tissues (Ellis *et al.*, 1991). Stable transformation of *P. abies* tissue was obtained following bombardment of mature somatic embryos with pRt99Gus (Robertson *et al.*, 1992). Stable transformation of *P. mariana* by particle

bombardment has been accomplished by Charest *et al.* (1996). An efficient particle bombardment has been developed by stably transforming several *P. abies* embryogenic tissue lines. Transgenic *P. abies* plants from nine independent transformation events were recovered and were growing in a greenhouse for future investigations (Walter *et al.*, 1999). In addition, pollen grain transformation by particle bombardment has been successful. The grains were transformed and a cone from a selected female was pollinated. The production of transgenic individuals in this way avoids the need for in vitro regeneration. Normal cone development has been reported in *Pinus aristata*, *Pinus griffithii*, *Pinus monticola*, and *P. abies* (Table 3). However, transgenic plants have not yet been produced, and regeneration of transformed embryos is proving to be difficult (Fernando *et al.*, 2000).

In *P. radiata*, a particle bombardment system was established by genetically transforming embryogenic tissue (Walter *et al.*, 1998). The average number of stable, geneticin-resistant lines recovered was 0.5 per 200 mg fresh weight bombarded tissue. Expression of the *uidA* reporter gene was detected histochemically and fluorimetrically in transformed embryogenic tissue and in derived mature somatic embryos and regenerated plants. More than 150 transgenic *P. radiata* plants were produced from 20 independent transformation experiments with four different embryogenic clones (Walter *et al.*, 1998). Using the same method, an efficient biolistic transformation technology was developed for *P. abies* (L.) Karst (Walter *et al.*, 1999). Stable integration of a *uidA* reporter gene and a kanamycin-resistance gene (*nptII*) into the genome of *P. abies* was achieved, and more than 200 mature embryos were regenerated for every transformation event. Transgenic *P. abies* plants from nine independent transformation events were recovered and were awaiting field release (Walter *et al.*, 1999; Tang and Newton, 2003, 2004; Tang *et al.*, 2004, 2005, 2006).

In addition, Clapham *et al.* (2000) established an efficient production method of transgenic plantlets of *P. abies* from embryogenic suspension cultures using a particle inflow gun (Finer *et al.*, 1992). Embryogenic colonies resistant to Basta appeared 2 months after bombardment. Of over 100 independent Basta-resistant sublines

tested, 65% expressed the co-transformed reporter gene, and over 80% of the sublines retained their embryogenic potential. Of 11 transformants analyzed, 4 contained transgenes in low copy number (1–3), the rest contained transgenes with up to 15–20 copies. Over 200 Basta-resistant sublines from four cell lines have been established, of which 138 are confirmed as transformed (Clapham *et al.*, 2000). Particle bombardment has also been used to produce transgenic plants in conifers for functional analysis of genes (Bishop-Hurley *et al.*, 2001) and promoters (Moyle *et al.*, 2002) and the development of early screening technologies for new introduced traits that promise to be of significant advantage to conifer biotechnology (Walter *et al.*, 2002).

2.5 Testing for Activity and Stability of Inheritance of the Gene, and Adverse Effects on Growth, Yield, and Quality

Applications of genetic engineering technology in tree physiology and biotechnology include: (1) alteration of tree form and performance, (2) insect resistance and herbicide resistance, (3) abiotic stress tolerance, and (4) modifying lignin content and composition. Insect resistance and herbicide resistance and modifying lignin content and composition have been widely studied in higher plants (Comai *et al.*, 1985; Bowler *et al.*, 1991; Baucher *et al.*, 1996; Pena and Sequin, 2001; Strauss *et al.*, 2001; Herschbach and Kopriva, 2002).

2.5.1 Gene expression

The activity of six different promoter-*GUS* (*uidA*) binary plasmid constructs has been analyzed in transgenic roots of *Pinus contorta* (Lindroth *et al.*, 1999). Transgenic roots were induced by infection with *A. rhizogenes* strain LBA9402, harboring a binary plasmid construct that contained one of the promoters: *Ubi-1* from *Zea mays*, 35S from CaMV, *cdc2a* and *sam-1* from *Arabidopsis thaliana*, *HRGPnt3* from *Nicotiana tabacum*, and *RSI-1* from *Lycopersicon esculentum* (Lindroth *et al.*, 1999). Promoters of broad tissue specificity (*cdc2a*, *Ubi-1*, and 35S) showed GUS staining in most cell types of all the species. The other three

promoters were expressed specifically in lateral root primordia. The studies of gene activity in primary transgenic roots allowed the screening of candidate promoters related to lateral and adventitious root formation within 3–6 weeks of inoculation in the angiosperm species and 2–3 months in *P. contorta* (Lindroth *et al.*, 1999). Recently, a putative promoter fragment of a *P. radiata* gene encoding a multifunctional *O*-methyltransferase (AEOMT) was isolated from genomic DNA (Moyle *et al.*, 2002). The isolated promoter was fused to the GUS reporter gene, and its expression profile was analyzed in transgenic tobacco and in transient transformation experiments with *P. radiata* embryogenic and xylogenic tissue. Histochemical analysis in transgenic tobacco plants revealed that the AEOMT promoter induced *uidA* expression in cell types associated with lignification, such as developing vessels, phloem and wood fibers, and xylem parenchyma as well as in nonlignifying phloem parenchyma (Moyle *et al.*, 2002).

Elfstrand *et al.* (2001) have studied the effects of an endogenous peroxidase-like gene from *P. abies*, *spi2*, on the development and growth of Norway spruce somatic embryo plants. Embryogenic cells transformed with *spi2* under control of the maize *ubi-1* promoter showed up to 40 times higher total peroxidase activity than the control cells; regenerated plants overexpressing *spi2* showed an increased total peroxidase activity (Elfstrand *et al.*, 2001). Overexpression of *spi2* resulted in increased sensitivity to stress, leading to a reduction in epicotyl formation and in height growth compared to control plants. Plants overexpressing *spi2* also showed a deeper phloroglucinol staining but similar levels of Klason lignin (Elfstrand *et al.*, 2001). In addition, adding extra copies of genes involved in *Agrobacterium* virulence and T-DNA transfer (*virG*, *virB*) to disarmed strains of *A. tumefaciens* increased transformation efficiencies for embryogenic *P. abies* (Wenck *et al.*, 1999).

2.5.2 Insect and herbicide resistance

Currently, insect resistance involves the introduction of a gene coding for *Bt* toxin from *Bacillus thuringiensis*. The *Bt* toxin inhibits the insect's digestive pathways. This gene has been successfully transformed into several species including larch

and conifers (Shin *et al.*, 1994) with varying degrees of success. Herbicide resistance has allowed the use of more efficient herbicides without concern for plant health in forestry, especially for higher intensity plantation systems. Herbicide resistance would be very useful especially in younger trees, where competition from weeds is the greatest (Shin *et al.*, 1994).

An example of herbicide resistance being introduced into a tree species is the work of Fillatti *et al.* (1987). A binary oncogenic strain of *A. tumefaciens* was introduced into a poplar clone. The strain carried a mutant gene (*aroA*), which codes for 5-enolpyruvylshikimate 3-phosphate (EPSP) synthase that is less susceptible to the herbicide glyphosate (N-phosphonomethylglycine) than the wild-type protein. Using a method of Reiss *et al.* (1984), the neomycin phosphotransferase II (NPTII) activity of the plant tissue was measured to determine whether the tissue had been completely transformed. Analysis of the introduction of the *aroA* gene, coding for the EPSP synthase enzyme less susceptible to glyphosate, was carried out using Western blot analysis after Comai *et al.* (1985). Recently, Bishop-Hurley *et al.* (2001) have established a biolistic transformation procedure where embryogenic tissues of *P. radiata* and *P. abies* were co-transformed with two plasmid DNAs that contained the *bar* (bialaphos resistance) gene, specifying resistance to the herbicide glufosinate, and the *nptII* gene and the *uidA* reporter gene, respectively. Regenerated plantlets from *P. radiata* and *P. abies* transgenic lines were spray tested with commercial rates of Buster (glufosinate at 0.5, 1.0, 2.0, and 3.0 kg active ingredient per hectare). Transgenic plants survived and continued to grow with minor or no damage to their needles, whereas nontransgenic plants regenerated from the same cell lines died within 8 weeks of spraying (Bishop-Hurley *et al.*, 2001).

2.5.3 Wood modification

Modification of wood by altering its chemical structure is a way of improving its properties. Research and development in this field has become increasingly important because wood is a renewable energy source and industrial material (Chiang, 2002; Doblin *et al.*, 2002). The wooden

cell wall consists mainly of polymers including cellulose, lignin, and hemicellulose (Doblin *et al.*, 2002). The reactive hydroxyl groups on these polymers are responsible for many physical and chemical properties of wood. The basic chemistry of the cell wall polymers can be altered by wood modification, which can change important properties of the wood including decreasing lignin content, increasing cellulose content, and improving durability, dimensional stability, and hardness (Chiang, 2002; Doblin *et al.*, 2002; Li *et al.*, 2003). Modern molecular genetics technologies have created new opportunities for wood modification (Chiang, 2002; Doblin *et al.*, 2002; Li *et al.*, 2003). At present several processes for modifying wood have been demonstrated on a laboratory scale and continued advances in process development will see these materials becoming more commonplace in the near future (Chiang, 2002; Li *et al.*, 2003).

Lignin is the second most abundant organic compound on earth, and represents about 25% of the global wood biomass (Leple *et al.*, 1992). Although lignin is an important compound for wood development, it is an obstacle to efficient pulp and paper production because the lignin must be removed in order to extract the cellulose from the wood (Pilate *et al.*, 2002). This process is energy consuming and requires the use of polluting chemicals. It is of great interest to try and engineer trees to have a lower lignin component or a lignin type that is easily extracted without reducing tree growth rates or bole form (Baucher *et al.*, 1996; Pilate *et al.*, 2002). Lignin is a group of compounds formed from three precursors: 4-hydroxycinnamyl-alcohol (p-coumaryl alcohol), coniferyl alcohol, and sinapyl alcohol. Field and pulping performances of transgenic trees with altered lignification have been reported (Pilate *et al.*, 2002). Conifers could be engineered with lower lignin content, or more syringyl lignin instead of the guaiacyl lignin, although there is no report in this area right now (Herschbach and Kopriva, 2002).

Cellulose is the major component of plant cell walls with secondary cell walls having a much higher content of cellulose (Doblin *et al.*, 2002). The relationship between cellulose and lignin biosynthesis is complicated, but it is confirmed that inhibition of lignin biosynthesis in transgenic trees will increase cellulose biosynthesis

and plant growth (Chiang, 2002; Doblin *et al.*, 2002; Li *et al.*, 2003). Both lignin quantity and reactivity may be regulated by distinct monolignol biosynthesis genes, encoding 4-coumarate-CoA ligase (4CL) and coniferaldehyde 5-hydroxylase (CAlD5H) (Chiang, 2002; Li *et al.*, 2003). Li *et al.* (2003) used *Agrobacterium* to co-transfer antisense 4CL and sense CAlD5H genes into aspen (*Populus tremuloides*). They found that lignin reduction by as much as 40% with 14% cellulose augmentation was achieved in antisense 4CL plants; increases as great as threefold in the syringyl/guaiacyl ratio were observed without change of lignin quantity in sense CAlD5H plants (Li *et al.*, 2003). An increase in syringyl/guaiacyl ratio also accelerated cell maturation in stem secondary xylem in transgenic aspen (Li *et al.*, 2003). Their results suggest that this multigene co-transfer system should be broadly useful for plant genetic engineering and functional genomics (Chiang, 2002; Li *et al.*, 2003).

2.5.4 Bioremediation

Phytoremediation, the use of transgenic plants to remove contaminants from soil or water, promises to have a positive impact on environmental pollution and, in the long term, the preservation of natural forests (Herschbach and Kopriva, 2002). Overexpression of the bacterial mercuric reductase in yellow poplar resulted in transgenic plants that were resistant to toxic levels of mercuric ions and were able to release elemental mercury (Rugh *et al.*, 1998). Currently, scientists at the University of Washington are trying to transform Loblolly pine with *A. tumefaciens* expression vector harboring the rabbit cytochrome *P450 2E1* gene for detoxification of soils contaminated with ethylenedibromide (M.P. Gordon, personal communication).

2.5.5 Flowering control

Although the major traits introduced into tree species have focused on insect resistance, low lignin, and enhanced growth (Pena and Sequin, 2001; Strauss *et al.*, 2001), there are several possible risks from transgenes to the native forest ecosystems (Mathews and Campbell, 2000).

Increasing knowledge about the control of flower development in trees opens up strategies to reduce or prevent the danger of vertical gene transfer to the wild tree species via genetic engineering of sterility (Strauss *et al.*, 1995). Another problem specific to tree species, compared to conventional agricultural crops, is the necessity for long-term stability of the transgene over several vegetation periods (Fladung, 1999; Kumar and Fladung, 2001). In addition, risk assessment investigations aimed at root–soil interactions, transfer of transgenes to wild plants, and possibility of horizontal gene transfer must be part of field trial assessment with transgenic trees as discussed by McLean and Charest (2000) and Strauss *et al.* (2001).

2.5.6 Future applications in tree physiology and molecular improvement

Tree transformation techniques allow direct testing of some hypotheses in tree physiology that have been exceedingly difficult to resolve using other biochemical approaches. Using transgenic trees, we can directly test the roles of specific enzymes in metabolic processes (Elfstrand *et al.*, 2001), the functions of different promoters (Lindroth *et al.*, 1999), and the influences of matrix attachment region on plant transformation and developmental processes (Levee *et al.*, 1999). We can also directly identify specific genes from genomic sequences. Tree transformation technique provides a powerful new experimental tool for tree molecular improvement. With this technology, transgenic trees with useful phenotypes unachievable by conventional tree breeding can be produced. Tree transformation also allows the commercial value of improved tree lines to be captured by industrial investors, such as commercial plant lines expressing foreign genes conferring resistance to viruses (James *et al.*, 1993, 1998; Birch, 1997). The extent to which the other practical or commercial expectations of plant transformation can be met depends on the efficiency and predictability of production of lines with the desired phenotype, and without undesired side effects from the transformation process (Birch, 1997; Tang and Newton, 2003, 2004; Tang *et al.*, 2004, 2005, 2006).

3. FUTURE ROAD MAP

3.1 Expected Products

Throughout human history, pines have provided a wealth of products beneficial to human society. The wood of many pine species has been used for structural lumber, production of paper and related products, fuel wood, posts, poles, and myriad other products. Pines have also provided a wide range of beneficial nonwood products including essential oils, resin, fragrant and attractive foliage, ornamental plants, decorative objects, edible seeds, flavorings, and medicinal products. In many cases, both wood and nonwood products from conifers have been overexploited to the point where extensive damage or loss of forest area has resulted. On the other hand, pines have been revered by many human cultures and have been used as both religious and political symbols. They are also the subject of a rich mythology and folklore and are well represented in arts. Genetic engineering of pine is expected to produce transgenic pines with novel traits such as (1) insect and herbicide resistance, (2) wood modification, (3) bioremediation, and (4) flowering control.

3.2 Addressing Risks and Concerns

Before the release of transgenic conifers to field, we have to achieve environmental and public acceptance. The activist groups see transgenic trees as setting a precedent toward broad and uncontrolled release of genetically modified plants in forests, and hence they are likely to fight vigorously against them (Strauss and Bradshaw, 2001; Fenning and Gershenzon, 2002). As long as ecological studies and development of improved options for genetic modification continue, we should find ourselves in a position to produce better kinds of transgenic trees, and have more answers to the questions being raised about their behavior in the environment. Although plant genomic research has been funded well in the United States to date, research support for plant genetic engineering risk assessment studies has been paltry by comparison (Strauss and Bradshaw, 2001).

The agencies primarily responsible for regulating biotechnology in the United States are

the US Department of Agriculture (USDA), the Environmental Protection Agency (EPA), and the Food and Drug Administration (Strauss and Bradshaw, 2001). Products from transgenic organisms are regulated according to their intended use, with some products falling under the remit of more than one agency. In the case of transgenic trees the agency responsible is the USDA; the EPA is also involved when modified traits may have an environmental impact. The USDA regulates novel plant release through its Animal Plant Health Inspection Agency (APHIS). Applicants for transgenic plants releases must provide details of the organism, the genes transformed, their products, and the purpose of release (James *et al.*, 1998; Strauss and Bradshaw, 2001). In the case of field trials, the experimental design and precautions against accidental escape of the transgenic trees must also be included in the application. APHIS may also demand special precautions such as closed containers for transport to field site and field cages to minimize the risk of pollen escape. APHIS permits for release into the environment are usually issued or denied within 120 days and during that time state officials will inspect the facilities to determine security and operating conditions. Permits for field trials are renewed annually. Before commercialization, genetically engineered plants must conform to standards set by State and Federal marketing statutes. There are no national requirements for varietal registration of new plants (Strauss and Bradshaw, 2001).

The feasibility of managing gene flow and minimizing the risks of genetic pollution appear only to have been considered in the United States and Japan, and only under certain conditions (Strauss and Bradshaw, 2001). Some of the regulations are decidedly short term, allowing trials to be strictly managed yet failing to make provision for the same safeguards at general release (James *et al.*, 1998; Fenning and Gershenzon, 2002). Perhaps most worrying is the fact that while the regulations are rightly concerned with biosafety issues, they tend to overlook the impact that fast-growing, long-lived plants may have on-site productivity. Transgenic super trees possess all the characteristics of a good weed and risk becoming invasives, and very fast growing, nutrient-demanding plantations operated on short rotations could drive inappropriate plantation

development. Many in the forestry industry, as well as academic researchers, are interested in genetically engineering trees but are proceeding cautiously as they evaluate the technology's environmental consequences and gauge how consumers will react to products made from genetically modified trees (Rogers and Parkes, 1995; Mullin and Bertrand, 1998; Fenning and Gershenzon, 2002; Tang and Newton, 2003, 2004; Tang *et al.*, 2004, 2005, 2006).

Forestry researchers are working on ways to create trees to resist pests, to make it easier to process pulp and paper products, and to assist in the restoration of endangered tree species (Strauss and Bradshaw, 2001; Fenning and Gershenzon, 2002). However, representatives from industry, academia, and environmental groups are expected to ask critical questions such as whether the benefits of developing genetically engineered trees outweigh any potential environmental risks, how broader historical and sociological factors play into the debate, whether current forestry practices will meet or exceed market demand for wood and paper products, and whether there should be changes in the regulatory process specific to the introduction of genetically engineered trees (Mullin and Bertrand, 1998; Strauss and Bradshaw, 2001), although questions about the potential ecological risks of introducing genetically engineered trees into the environment have been very complicated. In addition to examining the potential benefits and risks associated with genetically engineered trees, we also need to follow the current laws and regulatory practices that apply to the technology (James *et al.*, 1998; Fenning and Gershenzon, 2002). The potential environmental impacts of genetically engineered trees must be weighed against the costs of not pursuing the technology. Long-term field studies should be designed to examine not only novel gene stability and transgenic behavior but also tree crop-induced fluxes in soil nutrient status and soil water availability (Rogers and Parkes, 1995; James *et al.*, 1998; Mullin and Bertrand, 1998; Tang and Newton, 2003, 2004; Tang *et al.*, 2004, 2005, 2006).

3.3 Expected Technologies

Although particle bombardment and *Agrobacterium*-mediated gene transfer methods are now

sufficiently developed to allow transformation of essentially any plant species in which regenerable cells can be identified (Birch, 1997), the key to transformation of conifers (a group of recalcitrant species) appears to be development of methods to expose many regenerable cells to nondestructive gene transfer treatments because the frequencies of transformation in currently established transformation protocols are low and the frequencies of undesired genetic change or unpredictable transgene expression are high in some conifers (Walter *et al.*, 1998; Wenck *et al.*, 1999; Tang *et al.*, 2001). These constraints may be addressed by improving tissue culture systems to enrich for regenerable cells accessible to gene transfer, by developing techniques to allow rapid detection and optimization of transformation event, and by developing highly efficient selection techniques. In the longer term, a more important goal than increased transformation efficiency is the development of transformation methods and constructs tailored for predictable transgene expression, without collateral genetic damage (Birch, 1997). To achieve a high proportion of useful transformants, we need to understand more clearly the factors contributing to undesired genetic change during the transformation process.

Establishment of model transformation systems is very important in conifers. Although *Arabidopsis* is a widely used model system in plant biology because of its small genome, small plant size, and rapid generation time, the features that make this model attractive for some genetic studies cannot be generally exploited in practical transformation systems for conifers (Birch, 1997). As our understanding of the genetic basis of agronomic traits increases, it is likely that this goal will be extended to the introduction of greater lengths of DNA encoding multiple genes. We will need to determine the capacity of available methods to introduce such lengths of DNA intact. Some of these questions may not be answered with model plants; we have to be prepared to select the models according to the questions, and test the answers for applicability to the practical targets (Birch, 1997). Success in transformation of *Pinus radiata*, *P. strobus*, *P. taeda*, *P. abies*, *P. glauca*, and *P. mariana* provides good opportunities to develop a conifer model system from some of them (Walter *et al.*, 1998; Levee *et al.*, 1999; Wenck *et al.*, 1999; Klimaszewska *et al.*, 2001; Tang *et al.*, 2001).

Plant transformation is already sufficiently developed to allow the testing and even commercialization of plants with novel phenotypes under simple genetic control (Birch, 1997). However, our understanding of the biological basis for efficient conifer transformation and improved technologies for predictable transgene expression without collateral genetic damage need to be extended and developed (Walter *et al.*, 1998; Wenck *et al.*, 1999; Tang *et al.*, 2001). Exciting scientific advances in exploring the mechanism of *Agrobacterium*-mediated transformation have been made, but the whole process of gene transfer from bacteria to the nuclei of plant cells is not fully understood yet (Sheng and Citovsky, 1996). As transformation projects are increasingly undertaken with the possibility of generating commercially useful products, scientists in turn must increasingly integrate social, legal, and economic issues as well as technical issues from the earliest stages of project design (Birch, 1997; Tang and Newton, 2003, 2004; Tang *et al.*, 2004, 2005, 2006).

Tissue culture is not a theoretical prerequisite for plant transformation, but it is employed in almost all current practical transformation systems to achieve a workable efficiency of gene transfer, selection, and regeneration of transformants (Birch, 1997). Transformation protocols using particle bombardment (Birch and Bower, 1994) or *Agrobacterium* (Van Wordragen and Don, 1992) have been published based on practical experiences in laboratories working on recalcitrant species. Unfortunately, there is no guarantee that a transformable plant cell type will prove regenerable, even in the hands of the most successful tissue culturist (Birch, 1997). For transformation of a specific coniferous species, we need to pay attention to strategies for selection, transgene expression and integrating components of transformation. Screening approaches are expensive unless the transformation efficiency is high (Kim and Minamikawa, 1996). The features useful for the regulated expression of transgenes in plants include: (1) appropriate transcriptional promoters and enhancers (Benfey *et al.*, 1990), (2) transcriptional terminators and 3-enhancers (Richardson, 1993), (3) polyadenylation signals, untranslated 5-leader, and 3-trailer sequences (Turner and Foster, 1995; Wu *et al.*, 1995), (4) transit sequences for appropriate subcellular

compartmentation and stability of the gene product (Hicks *et al.*, 1995), and (5) cryptic introns resulting in inappropriate RNA processing (Perlak *et al.*, 1991; Reichel *et al.*, 1996). It is commonly generalized that *Agrobacterium* produces simpler integration patterns than direct gene transfer, but both particle bombardment and *Agrobacterium*-mediated transformation approaches result in a similar range of integration events, including truncations, rearrangements, and various copy numbers and insertion sites. Furthermore, the frequency distributions of copy number and rearrangements vary with transformation parameters for both gene transfer methods (Grevelding *et al.*, 1993).

3.4 Limitations and Changes of Technologies in Relation to Public Perceptions, Industrial Perspectives, and Political and Economic Consequences

Genomic studies have provided exciting opportunities for crop molecular breeding and plant improvement because the genomic sequences for model species are available and genetic transformation methods based on *Agrobacterium* and particle bombardment have resulted in the production of large numbers of primary transformants with normal morphology and stable transgene expression in short-term trials (Meilan *et al.*, 2000; Lucier *et al.*, 2001). Based on the information from genomic sequences, we are able to clone, express, and analyze functions of any single or multigene that are relative to a specific metabolic process, signal transduction pathway, storage product accumulation, cell division, plant growth and flowering, and seed development. However, it is unknown to what extent transformation causes less obvious genetic damage, such that transgenic clones might need to be re-evaluated in long-term field trials to verify that their yield and adaptability characteristics remain intact (Meilan *et al.*, 2000). Because most industries wish to see tested, well-known clones transformed and used directly, this is a critical issue for transgenic trees (Dekker-Robertson and Libby, 1998; Meilan *et al.*, 2000).

The major technical challenge facing tree transformation biology is the development of methods

and constructs to produce a high proportion of plants showing predictable transgene expression without collateral genetic damage (Rogers and Parkes, 1995; Birch, 1997). The issue of stability of gene expression is important not only for the maintenance of delivered traits, but may also be essential for obtaining regulatory and public approval for genetically modified trees through use of genes that impart floral sterility for gene containment (Birch, 1997). If engineered sterility is essential for commercial use, a breakdown in gene expression could have economic, environmental, and legal consequences (Strauss and Bradshaw, 2001). Gene silencing has been an active area of research in recent years, and it is becoming clear that many of the same mechanisms that act in silencing transgenes are also important for defense against viruses and invasive DNA elements (Fire *et al.*, 1998; Fire, 1999). However, little is known about the mechanisms of gene silencing and the factors that correlate with expression stability (Fire *et al.*, 1998). The extent of somaclonal variation and transgene instability is expected to vary depending on the specific transformation system, tree genotype, and vector/gene constructs employed (Birch, 1997; Fenning and Gershenzon, 2002). Therefore, studies are likely to be best accomplished via public scientists working in partnership with industries that are considering commercial use.

The insect- and herbicide-resistance genes widely used in crop biotechnology could be of considerable value for tree plantations and have been shown to be highly effective in transgenic trees (Meilan *et al.*, 2000). However, the engagement of academic and government scientists with industries wishing to commercialize transgenic trees is likely to be essential to convince a wary public that scientific assessments and plantation monitoring programs have been conducted responsibly (James *et al.*, 1998; Mullin and Bertrand, 1998). Another significant hurdle for use of transgenic technology in forestry is the Intellectual Property Rights that dominate the biotechnology sector (Lucier *et al.*, 2001). Even the major companies, which own large patent estates, are often in court with their competitors, fighting over access to major technologies, and several of these companies have chosen to use their patents as weapons to restrict access to technologies and to extend their sphere of control. The tight control of

technology and information by a few companies is itself a major driver of the high perception of risk associated with biotechnology (Strauss and Bradshaw, 2001; Fenning and Gershenzon, 2002). Unless there are major changes in government and corporate policy about control of intellectual property, industries are likely to continue to face a hostile public and a skeptical scientific community (Strauss and Bradshaw, 2001).

Particle bombardment and *Agrobacterium*-mediated transformation have been successfully used for a wide range of conifers including *Abies nordmaniana*, *L. decidua*, *P. abies*, *P. glauca*, *P. mariana*, *P. radiata*, *P. taeda*, *P. elliotii*, and *P. menziesii*. Production of genetically engineered conifers with commercially useful traits such as herbicide, insect, and pathogen resistance has been accomplished. Further development of gene transfer technologies for conifers will allow for the assessment of xylem-specific genes, promoters, and specific fungal-resistance genes in transgenic conifers, and the production of herbicide-resistant forest tree germplasm. These will develop to form commercially applicable technologies. Genetic engineering programs are focused on developing technology platforms and providing research services that lead to a better understanding of tree development and gene function. Forest research has been and is still firmly committed to playing a positive scientific role in the public debate concerning the application of genetic engineering technology in forestry and environmental biology. The techniques previously used for genetic transformation of agricultural plants are now finding their way into the engineering of forest tree species. At present, traditional breeding programs proceed at a slow rate due to long maturation times and the slow growth rate of trees; however, biotechnological approaches have the potential to provide significant improvement in tree growth and quality. If these problems can be addressed, forestry will enter a new era of productivity and quality.

1. INTRODUCTION

1.1 Distribution of the Genus *Picea*

The genus *Picea* A. Dietr. (spruce) consists of 34 species that are restricted to the northern hemisphere (Farjón, 1990). Most of the species occur in Asia, a couple of species in Europe, and up to 10 species in North America. Spruce has a transcontinental distribution in Asia, Europe, and North America. The transcontinental forest comprises the North American species, white spruce, *Picea glauca* (Moench) Voss; and black spruce, *Picea mariana* (Mill.) Britton *et al.*; and the Eurasian species, Norway spruce, *Picea abies* (L.) Karst.; and Siberian spruce, *Picea obovata* Ledeb. Other species are restricted to mountainous and subalpine regions (Wright, 1955; Rushforth, 1987; Farjón, 1990). Spruce species are adapted to a wide range of ecological habitats and climates. In the most northern latitudes of its distribution, where temperatures are low and the growing season is short, it is common to find pure stands of spruce. At warmer latitudes with longer growing seasons, spruce mixes with other deciduous angiosperm and gymnosperm species. During the cooler climate of the latest

ice age, an ice sheet spread across the northern hemisphere and had a great impact on species' distribution and population structure (Hewitt, 2004). In Europe, the mountain ranges of the Pyrenees and the Alps acted as barriers and thus caused a latitudinal dispersal, whereas in North America longitudinal mountain ranges and access to Central America made southward migration possible (Hewitt, 1996). The distribution of *Picea* today is largely influenced by the climatic oscillations during the Quaternary, and the effects on population structures and speciation have been studied (Lagercrantz and Ryman, 1990; Bucci and Vendramin, 2000; Vendramin *et al.*, 2000; Jaramillo-Correa *et al.*, 2004; Ledig *et al.*, 2004; Ran *et al.*, 2006).

1.2 Taxonomy

Spruce belongs to the family Pinaceae and the genus includes up to 34 species (Farjón, 2001; Ledig *et al.*, 2004). The intrageneric classification within *Picea* is considered difficult, and various authors differ as to species assignment to different subgroups. The relatively narrow range in morphology and ecological preference between species

and the high intraspecific morphological variation may compromise the reliability of the classification (Wright, 1955). Furthermore, many of the *Picea* species will hybridize in nature where species distributions overlap (Wright, 1955; Rushforth, 1987; Farjón, 1990). However, monophyly of *Picea* has never been debated (Wright, 1955; Rushforth, 1987; Sigurgeirsson and Szmidt, 1993).

Different subdivisions of the genus have been made on the basis of morphology and crossability studies. Many of the morphological characters overlap between species and there has been a lack of agreement on which trait to rely on. Traditionally, the genus is divided into three sections: *Picea*, *Casicta*, and *Omorika* (Schmidt-Vogt, 1977). Farjón (1990) divided *Picea* into sections: sect. *Picea* and sect. *Casicta*, each with two subsections (Table 1). Molecular approaches to resolve the intergeneric relationships of *Picea* do not support any of the previous subdivisions (Sigurgeirsson and Szmidt, 1993; Ran *et al.*, 2006). None of these authors suggest a new subdivision, but conclude that further studies are necessary.

1.3 Origin and History

Based on fossil records (LePage, 2001) and molecular clock estimation of the *matK* (maturase K) gene (Wang *et al.*, 2000), the origin of *Picea* could date back to the early Tertiary or late Cretaceous. The fossil record of *Picea* includes wood, leaves, cones, and seeds. The oldest record found is from Axel Heiberg Island in the Canadian Arctic and dates back to middle Eocene (ca. 45 million years BP) (LePage, 2001). The finding of three new fossil species at the Axel Heiberg Island also indicates that the genus had already diversified at that time (LePage, 2001). Most fossil findings from Asia are from the Oligocene, Miocene, and Pliocene, and the fossils found in Europe are even more recent, mostly from the Pliocene with one exception (LePage, 2001). Ledig *et al.* (2004) propose a North American origin for *Picea*, with migration to Asia across the Bering land bridge. They also suggest that the genus then spread from Asia further west to Europe, as the tropical to subtropical climate probably presented a barrier for dispersal through the DeGeer and Thulian Routes (Tiffney, 1985). Paleorecords contribute to evaluate species migration in response to climate

change; nevertheless, their accuracy is limited because of glacial refugia that are undetectable in fossil records (cryptic refugia). One example is the controversial unglaciated area extending from northeastern Siberia to the Yukon Territory. Recent genetic studies based on chloroplast DNA (cpDNA) support the existence of a glacial refuge in Alaska of white spruce (Anderson *et al.*, 2006). There are two main hypotheses regarding the origin of the genus (Wright, 1955; Sigurgeirsson and Szmidt, 1993; Ran *et al.*, 2006). Wright (1955) argues that the most likely center of origin is in Asia, with two independent migrations to the American continent. He bases his argument on the fact that Asia contains the largest species diversity, and that it harbors *P. koyamae*, which he considered to be the most basal species. However, these ideas conflict with the findings of Sigurgeirsson and Szmidt (1993) and Ran *et al.* (2006). The first molecular phylogeny of spruce at the genus level, using chloroplast DNA-restriction fragment length polymorphisms (cpDNA-RFLP), was constructed by Sigurgeirsson and Szmidt (1993) and their results indicate a North American origin. Based on a joint cp- and mtDNA (mitochondrial DNA) analysis, Ran *et al.* (2006) found, in agreement with Sigurgeirsson and Szmidt (1993) that the North American species Sitka (*P. sitchensis*) and Brewer spruce (*P. breweriana*) were basal to the other spruces in the phylogeny, and thus support a North American origin.

1.4 North American Species

Six of the 10 North American species occur in southwest United States and Mexico, and four are considered relicts (Ledig *et al.*, 2000, 2004). The economically important species, white and black spruce, are both found across northern North America and have a sympatric distribution. However, they have different habitat requirements, and natural hybridization has not been reported (Wright, 1955). White spruce has a more northern limit distribution. Attempts to introduce white spruce in Great Britain and Europe for reforestation have been unsuccessful in most cases. Red spruce (*P. rubens*) and Sitka spruce are also of significant economic importance and have a more restricted distribution. Red spruce's range covers Maine and surrounding territories and

Table 1 Subdivision and recognized species according to Farjón (1990)

Taxa	Common name	Distribution
Section <i>Picea</i>		
Subsection <i>Picea</i>		
<i>Picea abies</i> (L.) H. Karst.	Norway spruce	Europe
<i>P. alcoquiana</i> (Veitch ex Lindl.) Carrière		Japan
<i>P. asperata</i> Mast.		Asia

<i>P. engelmannii</i> Parry ex Engelm.	Engelmann spruce	North America
<i>P. pungens</i> Engelm.	Blue spruce	North America

extends along the Appalachians. Hybridization between red and black spruce has been described based on random amplified polymorphic DNA (Perron and Bousquet, 1997). Sitka spruce takes its name from Sitka, the former capital of Alaska when it was a Russian territory. It is found along the west coast from central Alaska to northern California (Rushforth, 1987; Farjón, 1990). A genetic analysis based on sequence-tagged polymorphism markers indicates that there is a zone of introgression between Sitka and white spruce in British Columbia (Bennuah *et al.*,

2004). Sitka spruce has become the most widely used conifer for reforestation purposes in Ireland, Wales, Scotland, and the Highlands, because the climate in its natural range is humid and mild, similar to that of western Great Britain. *P. pungens* grows in the Rocky Mountains, withstanding cold and hazardous winters, and hot and dry summers.

1.5 European Species

The most economically important conifer tree species in Europe is Norway spruce. Its natural

distribution ranges across the Pyrenees, Alps, and Balkans, northward to southern Germany and Scandinavia, and eastward through the Carpathian Mountains and Poland to western Russia (Rushforth, 1987; Farjón, 1990). Here, Norway spruce meets Siberian spruce in a broad hybridization zone. Siberian spruce then extends across northern Asia. The taxonomic relationship between Norway and Siberian spruce is still unresolved. A third species, Serbian spruce (*P. omorika*) is found in Serbia and Bosnia and is endemic in a restricted area along the Drina River. The two species, Serbian and Norway spruce, are usually mixed within the range of Serbian spruce (Farjón, 1990). However, they never hybridize in nature.

1.6 Asian and Japanese Species

Asia harbors most of the species diversity in the genus *Picea*. Farjón (1990) points out, together with other authors (see Farjón, 1990) that if more was known about many of the Asian spruce, some would be considered subspecies and varieties rather than species. Ran *et al.* (2006) include 19 species from Asia, and their results suggest a repeated dispersal to this area because they are polyphyletic. There are six species in Japan, four of which are endemic. In two previous molecular phylogenetic studies (Sigurgeirsson and Szmidt, 1993; Ran *et al.*, 2006), all the Japanese species were sampled. In both studies, those species were placed into different clades. This indicates that the Japanese species do not have a single origin (Ran *et al.*, 2006).

1.7 Cytology

There seems to be little karyotype differentiation between the species in the Pinaceae family (Murray, 1998). The diploid chromosome number in *Picea* is $2n = 24$ (Murray, 1998; Siljak-Yakovlev *et al.*, 2002; Vischi *et al.*, 2003). The genome size in Norway spruce and Serbian spruce has been estimated at $2C = 37.2$ pg (picogram) and 33.8 pg, respectively; and the GC (guanine-cytosine) content in both species is about 41% (Siljak-Yakovlev *et al.*, 2002). Depending on the method used and the sample, the DNA content

in white spruce varies from 17 to 14 pg and from 22 to 34 pg in black spruce (Murray, 1998). The genome size in Norway spruce corresponds to $2C = 30 \times 10^9$ bp (base pair) (Murray, 1998; Vischi *et al.*, 2003). The chromosome location of ribosomal DNA (rDNA) has been determined using fluorescent *in situ* hybridization and the variation in number of rDNA sites between species. In Norway spruce, six rDNA sites have been found (Siljak-Yakovlev *et al.*, 2002; Vischi *et al.*, 2003), whereas eight, seven, and five sites have been found for Serbian, white, and Sitka spruce, respectively.

1.8 Economic Importance and Industrial Uses

In Canada, forest cover spans 245 million hectares (Mha), well over two-fifths of its land mass; the most common tree species are white and black spruce. About 197 Mm^3 of industrial round wood were harvested in 2002 and the value of forest products exported in 2002 was US\$22.5 billion, whereas forest imports were valued at US\$4 billion. Major forest products include pulp and paper, lumber, veneer, plywood and particle board, and shingles and shakes. In the European Union (EU), about 127 of Union's 323 Mha—39% of its 323 Mha—is forest cover, varying from 10% in the United Kingdom to 50–60% in Austria, Finland, and Sweden. The EU forests are predominantly coniferous; 85% of them categorized as being seminatural, 10% intensively managed plantations, and only 5% natural stands. Total harvested wood for 2000 is estimated at 287 Mm^3 for the EU.

However, in the context of climate change, an increasing number of pests may target forest tree species, including spruce. The ecological ranges of existing pests could expand, and introduced exotic pests could also proliferate in these new environments. Therefore, proper strategies and mitigation processes for maintaining forest health must be elaborated. In this regard, tree biotechnology would have a significant impact (Fladung and Dietrich, 2006). Although not clearly quantifiable in economic terms, the impact of carbon sequestration from the forest would not be negligible. Finally, both natural and planted forests clearly play an

important role in maintaining water and wildlife resources.

1.9 Traditional Breeding: Objectives, Tools, and Strategies

Tree breeding aims to develop improved trees for economically important traits. Strictly speaking, conventional breeding is done by selecting and crossing trees at the individual level (Eriksson and Ekberg, 2001). In a wider sense, breeding also includes selection at the species and provenance levels. Conventional tree breeding is a cyclical process that relies on the extent of genetic variation. Genetic gains are obtained by selecting the best trees in the breeding population. Genetic gain is an estimate of the genetic improvement after selection, which is reflected in a phenotypic improvement. If the proportion of additive component of genetic variance is high, the genetic gain after selection of the best individuals is expected to be high. Selection in the breeding population (backward selection) is monitored by the results of the genetic evaluation of the progeny. Selection can also be performed on the best open-pollinated offspring (forward selection). The first step of a breeding program is to identify the objectives, which will differ depending on the final use of the improved material. Conventionally, forest tree breeding is based on the evaluation of such traits as growth and straightness. Other economically important traits related to wood quality and energy content are not usually included in breeding programs because they are too complex and expensive to achieve. Once the breeding objective has been identified, the next step is to estimate the additive genetic variance and expected genetic gain. Selection decreases genetic diversity in the improved population. Such an important issue has to be considered when designing a forest tree breeding program. For example, in Scots pine (*Pinus sylvestris* L.), which has large undomesticated populations, breeding programs contain a large amount of genetic diversity, and it has been estimated that the genetic gain can increase by 10% in a second-cycle breeding population without decreasing the genetic diversity (Ruotsalainen, 2002).

1.10 Limitations of Conventional Breeding and Rationale for Genetic Engineering

Conventional tree breeding has been proven to be very efficient for traits with high heritability, but is inefficient in certain cases such as when heritability is low, the evaluation of the trait is difficult or very time consuming, and juvenile period is too long. In general, a single breeding cycle may require some 25 years. The use of molecular markers to assist in tree breeding (marker-assisted selection, MAS) was proposed as a tool to shorten the period required and, consequently, improve the efficiency of conventional plant breeding programs (reviewed by Dekkers and Hospital, 2002). This technique consists of indirect selection for the desired trait in early stages using molecular markers. The most important question for efficient application of MAS is to find a tight linkage between markers and putative genomic regions controlling the trait (called as quantitative trait loci or QTL). Detection of a tight linkage requires a large number of progeny sets tested under different environments and developmental stages (Asíns, 2002). So far, the progenies used to develop markers to assist selection of desired QTLs have been based on too small progenies (around 100 individuals) and partially informative molecular markers (dominant markers, e.g., amplified fragment length polymorphisms, AFLPs). Thus, the QTLs identified and their linkage with flanking markers might not necessarily be consistent. The rapid advances in molecular genetics will help resolve the main limitations concerning the practical application of MAS. New molecular technologies are getting cheaper and therefore, molecular markers can be applied to a greater amount of material with a considerable improvement in statistical power to find consistent markers to be applied in MAS. Future possibilities and potential impact of MAS are considerable from the perspective of the newly developed tools and technologies. Despite this potential, there are limitations to the application of MAS because the linkage between marker and QTLs can be lost during the breeding cycle due to recombination. As an alternative, selection can be done directly on desired alleles of known-function gene markers (the candidate genes, CG). The hypothesis is that known-function genes linked to QTLs could correspond to the loci controlling those traits

(Pflieger *et al.*, 2001). This is a straightforward approach that avoids loss of the desired QTL during recombination and will allow breeders to select directly for the desired trait. This technique for selecting CGs linked to important traits is now available for pine species (*Pinus* spp.), and its use is likely to increase in the next few years in different forest tree species (Moran *et al.*, 2002; Brown *et al.*, 2003; Pot *et al.*, 2005; Yu *et al.*, 2006). The CG approach could bypass some of the limitations of the application of molecular markers in a tree breeding program. Nevertheless, despite the advantage of selecting on the CG, introgressing the right allele through a breeding cycle will still be a long process. Genetic engineering as a tool to introduce the desired alleles in the genome of spruce from identified breeding populations is a promising alternative that should shorten the time to produce new improved trees for desired traits. At this stage, however, much remains to be accomplished in the context of CG identification and social acceptance of genetically engineered trees (see below).

2. GENETIC TRANSFORMATION AND TRANSGENICS OF SPRUCE SPECIES

There are several prerequisites for the production of transgenic plants. First, the foreign DNA must be delivered to plant cells and it must integrate in the genome. These transgenic cells must then be selected and multiplied, and finally regenerate into a plant. Therefore, development of efficient gene delivery techniques based on efficient *in vitro* plant regeneration protocols is a prerequisite for production of transgenics in any species.

2.1 Target Tissue for Transformation of Spruce Species

The first successes in genetic transformation of spruces were made after the discovery of somatic embryogenesis (SE), a tissue culture process that results in production of somatic embryos that readily convert to plants (publications on SE: Chalupa, 1985; Hakman *et al.*, 1985; Hakman and Fowke, 1987; Webster *et al.*, 1990; and on transformation: Ellis *et al.*, 1993; Charest *et al.*,

1996; Walter *et al.*, 1999; Wenck *et al.*, 1999; Clapham *et al.*, 2000; Klimaszewska *et al.*, 2001, 2004; Le *et al.*, 2001; Lachance *et al.*, 2007). In spruces, SE has also become an indispensable tool for tree improvement programs because the embryogenic tissue (ET) can be readily stored in liquid nitrogen during lengthy clonal field tests (Cyr, 1999). Genetic engineering in spruces relies on SE as the target material for gene delivery and transgenic regeneration, because it offers many advantages. First, embryogenic tissue can be rapidly proliferated on either semisolid or liquid media, providing a source of actively dividing cells that are the most competent for genetic transformation. Moreover, these cells can be easily handled in suspension culture and on various supports at very low cell densities that facilitate effective selection of transformed cells. Second, occurrence of chimeras is rare because a somatic embryo is usually derived from a single cell (Klimaszewska *et al.*, 2003). Third, it takes a relatively short time to recover a transgenic plant through SE. Finally, another significant advantage of SE is that a transformed embryogenic tissue line can be easily cryopreserved without any detectable effect on regrowth and transgene expression. This feature is critical because embryogenic cultures can progressively lose their somatic embryo maturation ability during the prolonged tissue culture period, or may get contaminated. Furthermore, high transformation efficiency is necessary for cost-effective, large-scale production of transgenic material needed for the high-throughput gene testing or extensive screening and final selection of lines that might eventually be accepted for commercial deployment. For all these reasons, in this review we focus on the protocols developed specifically for transformation of spruce embryogenic cells.

2.1.1 Somatic embryogenesis

Somatic embryogenesis in spruces is routinely initiated from immature or mature zygotic embryos; the formers are usually cultured enclosed in the megagametophytes. On average, the initiation frequency is always higher from immature embryos compared with mature embryos excised from either freshly collected or stored seed. This

response also varies depending on the species, exact developmental stage of an embryo, and the seed family, and can reach 20–80% (Cheliak and Klimaszewska, 1991; Park *et al.*, 1993; Högberg *et al.*, 1998). Explants from spruce plants have also been used to induce SE, with the oldest tree being a 3-year-old Norway spruce (Harvengt *et al.*, 2001). However, only the seed explants provide practical SE initiation efficiencies and ease of handling.

The most frequently used nutrient media for spruce SE include the one described by von Arnold and Eriksson (1981) or by Litvay *et al.* (1985). Media are supplemented with organic nitrogen (L-glutamine and casein hydrolyzate). For SE initiation and proliferation, the media typically contain 2,4-dichlorophenoxyacetic acid at 9.0–10 μM and benzyl adenine at 4.5–5.0 μM , and sucrose at 1% or 2%, and they are solidified with agar (0.8%) or gellan gum (0.4%). The somatic embryos remain at the early developmental stage (Figure 1a) unless subcultured onto a medium with abscisic acid (ABA) at 20–60 μM on which they mature after 5–7 weeks of culture. Spruce species respond to several maturation protocols: one of the more efficient was tested with three species and involved culture of the embryo masses in a layer spread over a filter paper disk (Whatman No. 2) placed on MLV, modified Litvay medium (Litvay *et al.*, 1985), with 60 μM ABA, 6% sucrose, and 0.6% gellan gum (PhytigelTM) (Klimaszewska *et al.*, 2001). After 7 weeks, the embryos (Figure 1b) were harvested and germinated at a high frequency on a medium without plant growth regulators and with 2% sucrose and 0.6% gellan gum. Somatic plants were developed after 3–4 months, and at this stage were moved *ex vitro*.

2.1.2 Cryopreservation

Long-term storage of spruce ET at ultra-low temperatures (–140 to –196 °C) is a routine and integral element of any SE program. Since the first publication on cryopreservation of white spruce ET by Kartha *et al.* (1988), the protocol has been modified for use with other spruce species. One of the current protocols entails incubating 2 g fresh mass embryogenic tissue in 7 ml of liquid culture medium (of the same composition as for

maintaining the growth of ET), supplemented with 0.4 M sorbitol for a period of 18–24 h. All subsequent steps are carried out on ice. Just before freezing, cold DMSO (dimethyl sulfoxide) solution (in a culture medium) is added to the cell suspensions to a final concentration of 5–10% (v/v). The cell suspension is then left on ice for 1 or 2 h, and then dispensed into cryovials, which are placed in alcohol-insulated containers that are pre-cooled for 2 h at –80 °C. The containers with vials are then placed at –80 °C for 1–2 h, during which a slow cooling of the cell suspension (approximately –1 °C min^{–1}) takes place. The vials are subsequently plunged into liquid nitrogen and stored in a cryofreezer. For regeneration, the contents of the vials are rapidly thawed in a water bath at 37 °C for 1–2 min and the cell suspension is poured over a filter paper disk placed on a thick pad of sterile blotting paper. The storage solution is allowed to drain for several minutes and the filter paper with cells is transferred onto semisolid medium. Growth of cultures typically occurs within 1–2 weeks after thawing.

2.1.3 Genetic transformation

The media for transformation and selection processes of transformed cells in spruces are usually the same as those used for ET proliferation, with appropriate modifications or additives (Klimaszewska *et al.*, 2004). Once transgenic clonal lines (transclones) are selected and stabilized, the cryopreservation, maturation, and germination of somatic embryos, as well as conversion to transformed plants (Figure 1c) follow the same protocols as developed for SE of each spruce species. The most frequently used gene delivery methods for stable transformation of spruces are DNA-coated particle bombardment (PB) and co-culture of cells or explants with disarmed strains of *Agrobacterium tumefaciens* (AT, *Agrobacterium*-mediated transformation). PB is a direct transformation method that involves bombarding the plant cells with small metallic particles coated with the gene(s) of interest. After the particles enter a cell, providing the cell remains viable, the foreign DNA randomly integrates into the genome. In the AT method, the gene(s)

Figure 1 Genetic transformation of *Picea glauca* through co-cultivation with *Agrobacterium tumefaciens*: (a) selection of transformed cell colonies on a medium with kanamycin with an inset showing higher magnification (20 \times), (b) mature transgenic somatic embryos (magnification 8 \times), (c) expression of *uidA* by transgenic somatic seedlings visible following X-gluc histochemical assay (magnification 2.5 \times), (d) transgenic somatic seedlings in the greenhouse

of interest is inserted into the transfer-DNA (T-DNA) region of tumor-inducing plasmid (pTi) from a disarmed *A. tumefaciens* strain. After contact and attachment of bacteria to plant cells, the T-DNA is transferred to the nucleus and then stably integrated into plant genome (Tzfira *et al.*, 2004).

Transformation efficiency of spruces is affected by a number of factors related to the plant material, e.g., species, genotype, explant type, and source, as well as the developmental and physiological state of target tissue. A number of methodological issues are also critical for successful transformation and regeneration of any transformed plant, namely, the gene delivery method (AT or PB), the selection procedure of transformed cells, and the stress recovery following either physical damage caused by

particle bombardment or *Agrobacterium* infection. As well, physiological damage may occur during the long process of transformation and selection.

2.2 Transformation Using Particle Bombardment

White spruce was the first transgenic spruce species produced after PB transformation of mature somatic embryos that regenerated plants through secondary SE (Ellis *et al.*, 1993). Since this key report, protocols have been developed to produce transgenic plants in two other spruce species: black spruce (Charest *et al.*, 1996; Tian *et al.*, 2000) and Norway spruce (Walter *et al.*, 1999; Clapham *et al.*, 2000). As a physical method of gene transfer,

PB optimization mainly relies on modification of bombardment parameters such as microcarrier particle size and speed, distance to target, use of filter paper as a support to anchor the cells, and preculture of cells on preparation media to preserve cell integrity (Altpeter *et al.*, 2005). This direct, practical, and rapid physical method to deliver foreign DNA into the cells is considered to be independent of genotype, especially in transient gene expression experiments. Moreover, a gene construct could be delivered into virtually any organ, tissue, cell, or even cell compartment. Thus, this method appears best suited for large-scale studies of transient gene expression, such as promoter testing.

2.3 Transformation Using *A. tumefaciens*

The first success in AT transformation of a conifer and regeneration of transgenic plants was achieved by Levée *et al.* (1997) in hybrid larch (*Larix* spp.). Since then, AT has become the preferred method for spruce transformation rather than PB (Wenck *et al.*, 1999; Klimaszewska *et al.*, 2001; Le *et al.*, 2001). For example, it is presently being used exclusively for a functional genomics study in white spruce under the Arborea phase I project (<http://www.arborea.ca>). Over 20 different gene constructs were stably integrated and several translines for each construct were obtained. Combined with SE technology, close to 2000 transgenic trees were produced. One of the reasons for using the AT method of transformation is that it usually results in more predictable transgene integration patterns, with a higher frequency of single-copy and single-locus insertion events, and with less transgene fragmentation and rearrangement. The single insertion events tend to result in stable gene expression, whereas integration of multiple copies of a transgene may lead to both transcriptional (TGS) and post-transcriptional gene silencing (PTGS) (Hamilton and Baulcombe, 1999; Meyer, 2000).

Improvement of AT methodology requires that conditions for interaction of bacteria with plant cells, strains of *A. tumefaciens*, access to plant cells (wounding, vacuum infiltration), and co-cultivation parameters (plant cell and bacteria preparation, density ratios, duration, temperature, bacterial virulence inducers) be

optimized. Furthermore, after transformation is completed, the agrobacteria must be eliminated from the cultures before the subsequent *in vitro* steps of selection and regeneration of transformed plant material. It is also an important objective for field release of transgenic trees (see Section 3). The main concern is that the modified, laboratory strain of *A. tumefaciens* could be released into the soil from the roots of the transgenic host plant and subsequently infect other plants or transfer the genes to other microorganisms by horizontal gene transfer (Droege *et al.*, 1999; Stewart *et al.*, 2000). The persistence of *A. tumefaciens* in genetically engineered trees is of significant interest, because they are likely to remain in the environment for decades. Unfortunately, there are disproportionately fewer publications investigating the survival of residual *A. tumefaciens* in plant tissues after transformation, relative to those on transformation itself. However, a few studies have reported that *A. tumefaciens* persisted in the tissues of other transgenic plant species (herbaceous and trees) for up to 3 months after transformation (Mogilner *et al.*, 1993; Cubero and López, 2005). Recent studies on residual agrobacteria after transformation of ET of several conifer species including white spruce showed it to persist for up to 12 months despite the lack of visible bacterial growth on the culture medium (Charity and Klimaszewska, 2005). However, no agrobacteria were detected in mature somatic embryos or in needles, branches, stems, or roots of transformed plants grown in a greenhouse (Figure 1d) for up to 4 years following transformation. One of the critical issues that became apparent in that study was the limitations of the polymerase chain reaction (PCR) in detecting bacterial DNA in a background of pine needle DNA, which was approximately 10^9 – 10^{10} cells per gram fresh mass of tissue. Thus, rather than using the PCR method as the sole detection technique when determining if *A. tumefaciens* persists in plant tissues, it is recommended that an enrichment culture of bacterial cells released from macerated plant tissues on bacterial growth medium, followed by PCR of bacterial colonies, be used; Cubero and López (2005) also reached at this conclusion. Various strains have been tested in spruce transformation, such as succinamopine strains with C58 chromosomal background (EHA105, AGL1), octopine TiAch5 (LBA4404) or C58

(GV2260) strains, and various nopaline C58 strains such as EHA101, GV3101, C58pMP90 (= GV3101pMP90), and GV3850 (Hellens *et al.*, 2000).

2.4 Selection and Reporter Genes

As in most other plants, the success of transformation in spruce species depends on the efficient delivery and expression of selectable marker genes that subsequently allow selection of the transformed cells. Only negative selection with antibiotic- or herbicide-resistant genes has been reported in spruce. Three selection genes have been employed in stable transformation studies: (1) the commonly used *nptII* (neomycin phosphotransferase II) gene from *Escherichia coli* encoding neomycin phosphotransferase, which confers resistance to the antibiotics kanamycin or geneticin, (2) the *hpt* (hygromycin phosphotransferase) (or *aphIV*, aminoglycoside 3'-phosphotransferase IV) gene from *E. coli* encoding hygromycin phosphotransferase, an enzyme capable of detoxifying hygromycin B, a strong inhibitor of protein synthesis, and (3) the *bar* (bialaphos resistance) gene isolated from *Streptomyces* spp., encoding the phosphinothricin acetyl transferase responsible for resistance to phosphinothricin and bialaphos or the commercial herbicide formulations BastaTM or BusterTM. In each case, it is necessary to determine the optimal concentration of the chemical for effective selection of transformed cells. These concentrations are usually specific for each spruce species and type of target explant in order to allow selection of transformed cells while preserving their regeneration potential. Inefficient application (type, concentration, and timing of selection after transformation) of the selective agent may result in conditions that are toxic to both transformed and nontransformed cells, or that are insufficiently stringent, resulting in high frequency of nontransformed cells escaping the selection process (escapes).

Reporter genes facilitate visualization and quantification of gene expression by means of bioassays. The most frequently used genes are *uidA* (encoding β -glucuronidase) and *gfp* (encoding green fluorescent protein). Nontoxic, visual marker genes such as *gfp* may be useful in developing effective selection strategies for

transformed cells at the early stages without the need for antibiotic or other selective agent application.

2.5 Promoters, Gene Expression, and Silencing

Several constitutive promoters, such as CaMV 35S (cauliflower mosaic virus 35S), *nos* (nopaline synthase), *ubi* (maize *ubiquitin*), artificial *Emu*, and rice *actin*, have been used to control gene expression. In fact, these promoters have been tested in several coniferous species including pines and spruces (Tang and Newton, 2003). Overall, it was possible to achieve good levels of transgene expression, and in one case, long-term expression over 5 years was achieved in *P. glauca* using the *ubi* as well as the CaMV 35S promoters (Lachance *et al.*, 2007). In one specific study by Tian *et al.* (2003), constitutive expression of a tobacco cryptic promoter, *tCUP*, was demonstrated in white spruce. These data, together with other promoter evaluation in spruces, suggest that conifers (gymnosperms), despite their evolutionary history, can recognize 5' regulatory sequences derived from angiosperm.

Nevertheless, inducible promoters were proposed to offer more flexibility, as they allow the regulation of gene expression (reviewed by Gatz, 1997). Functional studies would benefit from the availability of a system to induce gene expression at defined developmental stages or under particular conditions. These promoters are quiescent in the absence of inducers, and therefore, ectopic transgene expression will not interfere with physiological activities and plant regeneration while the promoter is inactive. This approach is particularly important to obtain overexpression of a gene with regulatory function.

2.6 Targets for Genetic Engineering of Spruce

Recent reviews thoroughly described the potential applications of forest tree biotechnology, including genetic engineering (Boerjan, 2005; Nehra *et al.*, 2005; Fladung and Dietrich, 2006). Despite their wide ecological range and economical importance, relatively few studies have dealt with genetic

modification for adaptative or economical traits of spruces. Far more work has been done in coniferous species, such as pine, or hardwoods, such as poplar (*Populus* spp.). Nevertheless, successful approaches for increasing insect and microbial pathogen resistance were achieved. An endochitinase gene from the biocontrol fungus *Trichoderma harzianum* was stably expressed in black spruce and translines showed an increased resistance to the spruce root pathogen *Cylindrocladium floridanum* (Noël *et al.*, 2005). More recently, insect resistance using a *Bacillus thuringiensis* (*Bt*) synthetic gene was achieved in white spruce (Lachance *et al.*, 2007). Several translines engineered with the *Bt Cry1Ab* endotoxin gene showed total resistance in several insect feeding assays with the spruce budworm (*Choristoneura fumiferana*). A unique feature of this work pertained to a 5-year field trial that showed long-term stability of transgene expression. Interestingly, strong *Cry1Ab* gene expressing lines identified early in the selection process (young somatic seedlings) also showed strong *Bt* transgene expression after several growing seasons in the field.

2.7 From Single Gene Transformation to Functional Genomics

Biological processes of tree growth, development, reproduction, and defense are orchestrated by genetically programmed mechanisms, fine tuned to respond and adapt to environmental conditions. Several studies, mainly in model plant systems, have uncovered a gene whose putative biochemical function and expression patterns may be linked to specific processes of interest in plants. Gene functional analyses by overexpression have been used in a limited number of publications dealing with forest tree species, mainly in poplar (Campbell *et al.*, 2003). To overcome the complexity of the peroxidase isoenzyme family, a Norway spruce peroxidaselike gene, *spi 2*, was studied by ectopic expression using the ubiquitin promoter (Elfstrand *et al.*, 2001). Transgenic *spi 2* expressing Norway spruce lines showed up to 40 times higher total peroxidase activity, confirming the function of *spi 2*. Despite some negative physiological effects of *spi 2* overexpression, such as embryogenic development defects, transgenic trees were regenerated. These were significantly shorter and showed more intense

phloroglucinol staining in the xylem, but no measurable differences in lignin content compared with wild-type trees.

The fact that gene function is investigated individually provides only a limited view of the molecular landscape of the cell as well as the complexity of protein action and interactions. An important advantage derived from functional genomics approaches is the depth of analysis that may be accomplished through large-scale investigations of gene and protein functions. In recent years, continuous new technological platforms have appeared and created diverse opportunities for genome-scale gene discovery and expression studies, focusing largely on RNA transcripts, also referred to as the transcriptome.

To date, most gene studies based on loss or gain of function experiments in trees have been investigated in transgenic poplars. Poplar has traditionally been the tree of choice because of its ease with transformation procedures, but significant progress, as described above, has been made in the development of reliable protocols for commercially valuable conifers such as pine and spruce. The opportunity now exists to develop a genome-wide vision of gene function in trees with genomics resources that are being developed. During the last 5 years, two important forest genomics projects, Treenomix (<http://www.treenomix.ca>) and Arborea (<http://www.arborea.ca>), have developed important resources by establishing databases containing a large number of expressed sequence tags for spruces. These projects not only provided a valuable starting point for genomics studies on conifer species, but allow investigation in the field of metabolomics and functional genomics.

3. DEPLOYMENT OF TRANSGENIC TREES IN THE CONTEXT OF MULTIVARIETAL FORESTRY AND BIOSAFETY ISSUES

Owing to the recent achievements in SE of spruce species, its commercial potential has been explored (Adams *et al.*, 1994), and the deployment of trees produced by SE has begun. Although SE is the primary enabling technology for genetic transformation, its most important application is in implementing multivarietal forestry (MVF), which is defined as the deployment of tested tree

varieties in plantation forestry. It is also called clonal forestry, but with advances in conifer SE, MVF is considered to be a more descriptive term when applied to commercial plantation forestry (Park, 2004). In general, a clone refers to a genotype with its genetic copies or ramets, whereas a variety refers to a clone that has been selectively bred for certain attributes as in an agricultural variety. The implementation of MVF offers many advantages, and some important ones are as follows: (1) much greater genetic gain than from conventional tree breeding based on seed orchards, (2) flexibility to rapidly deploy suitable varieties with changing breeding goals and environments, and (3) ability to design and balance genetic gain and diversity in plantations.

3.1 Commercial and Ecological Applications

In order to practice MVF, it is essential that high-value tree varieties be developed. Development of high-value SE varieties is usually closely coordinated with multigeneration tree breeding programs, which generally adapt a form of recurrent selection and manage breeding populations for the next generation. In many well-established programs, the nucleus breeding strategy is used, involving a hierarchical structuring of the breeding population, where the top tier contains the elite (nucleus) parents. This strategy is adapted to obtain fast delivery of genetic gain from the elite crosses (Lstibůrek *et al.*, 2004). Therefore, it is best to start varietal development with the nucleus population using a system of controlled crosses. In typical tree breeding programs, controlled crosses among the selected elite parents will be performed to produce offspring. The resulting seeds are then subjected to SE initiation to develop SE lines. Once embryogenic lines are developed and proliferated, they are stored in liquid nitrogen, while field tests are established using the embryogenic lines retrieved from cryogenic storage. Field testing is the most important part of MVF and is essentially the process for identifying tree varieties for deployment. This provides an opportunity to produce genetically tested identical genotypes consistently over time, which is analogous to the production of agricultural varieties. In eastern Canada, for example, over 3000 embryogenic

varieties of spruces, including white, black, red, and Norway spruce, are tested in the field. The current annual deployment in MVF is at about 750 000 trees on selected sites, but the number is steadily increasing (G. Adams, JD Irving, Ltd, personal communication).

Potential benefits and recent advances in genetic transformation technology have led to intense interest in using the technology in commercial forestry, such as MVF. It is envisaged that genetic transformation is likely to be applied to already improved tree varieties as a value-added component of MVF. Since the introduction of value-added transgenic varieties is mainly to be within the context of MVF, it is important to develop ecologically sound MVF strategies before deploying transgenics trees. Therefore, all aspects of the general requirements for implementing MVF are equally applicable for deploying transgenic trees. The current MVF strategy using SE and cryopreservation is based on careful exploitation of indigenous genetic variability that exists in nature. However, the deployment of transgenic trees requires additional attention because when new foreign genes are introduced, gene function has been substantially altered. Therefore, it is important to critically evaluate and manage potential risks before transgenics are deployed.

3.2 Managing Biodiversity

In MVF, the management of diversity is a concern because of the perception that a narrow genetic base may result in MVF plantations being more vulnerable to diseases and insects than seedling plantations, and ultimately in plantation failure. For known diseases and insects, MVF has an advantage because resistant varieties may be developed in combination with improved economic traits. But, for unknown or introduced diseases and insects, protection is limited despite the high degree of genetic variability existing among forest trees. It is difficult, if not impossible, to design a protection scheme against unknown pests. However, it is generally assumed that the more varieties deployed in a plantation, the lower is the risk. The use of an increased number of varieties in a plantation will reduce genetic gain, so it will be necessary to balance

genetic gain and diversity, leading to the question of what is an appropriate number of varieties in an MVF plantation (Libby, 1982). This is a difficult question; however, using various approaches, scientists generally agree that 10–30 varieties mixed in a plantation should be sufficient for protection and still yield the benefits of MVF (Libby, 1982; Hühn, 1987; Zobel, 1993; Roberds and Bisher, 1997). Once an appropriate number of varieties is decided, the MVF strategy must consider the configuration of the deployed varieties, either as a random mixture or in varietal blocks (Libby, 1982). In general, a random mixture is appropriate when varieties are not well known or future pest situations are uncertain (Lindgren, 1993).

3.3 Regulatory Consideration

The purposes of using genetic transformation technology in forest trees include the incorporation of new genetic traits that are not accessible by the natural mode of breeding and the regulation of gene expression, such as gene silencing and overexpression. Potential benefits of transgenic trees in the context of MVF include the following: (1) increased ecological competence by engineering transgenes conferring resistance to diseases, insect attack, and abiotic factors such as drought and cold stress and herbicides (Tang and Newton, 2003); (2) improved product quality and productivity by modifying gene expression (Nehra *et al.*, 2005); and (3) derivation of new products (Mullin and Bertrand, 1998).

It is likely that the conferring of disease and insect resistance through transgenic technology will enhance MVF; however, additional biosafety issues have been identified for transgenic deployment. The major concern has been the possible spread of transgenes from transformed varieties to natural populations or related organisms. The obvious mode of gene flow is sexual reproduction through windborne pollen, which is difficult to control. Isolation barriers have been suggested, but these are likely to be only partially effective. Genetic engineering of flowering sterility (Strauss *et al.*, 1995) seems to be an attractive option to incorporate employing transformation, but it is extremely difficult to ensure the stability of the sterility, especially in view of forest trees' long

rotations (Mullin and Bertrand, 1998). Another concern about the escaped genes is the change in invasiveness due to the selective advantage conferred by the transgene (Dale, 1992; Raybould and Gray, 1994). Even if the transgene does not escape, it still may have an adverse effect on other organisms because of possible toxicological effects when consumed by other organisms or through nutrient recycling (Mullin and Bertrand, 1998). The introduction of novel traits by genetic transformation may lead to changes in forest management that could have an impact on ecosystem processes. The extensive use of value-added transgenic trees may reduce diversity, even further leading to the deployment of a single or only a few genotypes. Therefore, a scientifically sound management plan for plantation diversity in the context of MVF should be applied.

Even when a great deal is known about a transgenic line, an absolute guarantee of safety is not possible. Risk assessment in relation to the deployment of transgenic trees is needed to evaluate the risk management strategies intended to minimize risks (Mullin and Bertrand, 1998). Such risks trigger the regulation of environmental release in many jurisdictions. Transgenic trees require rigorous testing before they are released into the environment. Assessment at initial stages is usually performed in the laboratory, growth chamber, or greenhouse. Once transgenic plants show promise, the next step is to conduct a field test under confined conditions to restrict unintended consequences. The confined field trial phase is an important step for collecting relevant data on the characteristics of transgenic plants and biosafety evaluations. In many jurisdictions, e.g., Canada and the United States, a permit is required to conduct a confined field test and researchers must abide by its terms and conditions. Typically, a confined field test is reproductively isolated and requires monitoring of trial sites for current and postharvesting periods. After several years of a confined field trial, an unconfined environmental release may be approved. Approval is usually based on a thorough environmental safety assessment completed according to rigorous, internationally accepted procedure using the most current scientific knowledge (Finstad *et al.*, 2007).

In Canada, environmental release of plants with novel traits (PNT, includes transgenic trees) is regulated by the Plant Biosafety Office of the

Canadian Food Inspection Agency. In Europe, the European Community (EC) imposes strict rules on genetically modified (GM) organisms, and GM trees may only be introduced into the environment in conformity with Directive, 2001/18/EC. This directive and supplemental decisions provide detailed guidance on the objective, elements, general principles, and methodology of full environmental risk assessment. Provisions for risk assessment are founded on comprehensive scientific evaluation by each member state within the EC. In the United States, transgenic trees are regulated by the Animal and Plant Health Inspection Service (APHIS). Developers of transgenic trees must obtain prior authorization from APHIS for import, interstate transport, and field testing of these plants. Field testing is a precondition of deregulation, which is necessary for the transgenic trees to be commercialized (Sedjo, 2004).

Transgenic trees are the product of a powerful technology that promises many benefits. It is important to capture those benefits while ensuring public safety and maintaining environmental integrity. The deployment of transgenic trees is also a social issue and, despite scientific endeavors, there are knowledge gaps in developing an effective assessment and management of biosafety. This is an appropriate time to open dialog among scientists, the public, and regulators for careful integration of this powerful technology in forestry.

1. INTRODUCTION

1.1 History, Origin, and Distribution of *Castanea*

The *Castanea* genus is a member of the family Fagaceae. The fossil record indicates that Fagaceae was already well established by the Eocene (35–55 million years before present (BP)) and may have arisen in the Paleocene (55–65 million years BP) (Crepet and Nixon, 1989a, b; Kvacek and Walther, 1989). Fagaceae is divided into four subfamilies, seven genera, and approximately 1000 species. The first three subfamilies, Fagoideae, Trigonobalanoiceae, and Quercioideae, each contain a single genus, *Fagus*, *Trigonobalanus*, and *Quercus*, respectively (Jones, 1986). The fourth subfamily, Castaneoideae, is made up of four genera, *Chrysolepis* (2 species), *Castanopsis* (approximately 30 to 100 species), *Lithocarpus* (approximately 300 species), and *Castanea* (approximately 7 species) (Johnson, 1988).

One of the smallest genera in the Fagaceae family, *Castanea* is discontinuously distributed throughout the temperate regions of the northern hemisphere. Fossil evidences from Greenland, Alaska, and western North America indicate that this genus was once more widespread than at present (Jones, 1986; Lang *et al.*, 2007). The

Castanea genus is divided into three sections, *Eucastanon* (chestnuts) with five species: *Castanea mollissima* Blume, *Castanea sativa* P. Mill., *Castanea crenata* Sieb and Zucc., *Castanea dentata* (Marsh.) Borkh., and *Castanea seguinii*; *Balanocastanon* (chinkapin) with one species: *Castanea pumila* (L.) P. Mill.; and *Hypocastanon* (Henry chestnut or willow-leaf chestnut) with one species: *Castanea henryi* (Rutter *et al.*, 1990). The two main species discussed in this review, European chestnut (*C. sativa*) and American chestnut (*C. dentata*), both grow to large sizes and have a maximum lifespan of several centuries.

1.2 *C. sativa* Mill. (Sweet Chestnut, European Chestnut)

European chestnut is a tree species with a wide distribution and an important economic role in Europe. It is present in 25 European countries, covering an area of over 2 million hectares (Conedera *et al.*, 2004). *C. sativa* is considered the only native chestnut species in Europe. The trees are large (20–25 m in height) and spreading with a compact crown, and the nuts are normally larger than those produced by other *Castanea* species.

European chestnut probably originated in the Caucasus Mountains, between the Black and Caspian seas, and it is thought that the

Ponto-Caucasian region is the main genetic source of the species (Villani *et al.*, 1999). Palynological data (Huntley and Birks, 1983) indicate that *C. sativa* was widely distributed during the Tertiary period, being restricted to the southern refugia after successive glaciations. The pollen record also indicates a second, rapid expansion linked to human activity through the expansion of the Roman Empire, starting more than 2000 years ago (Robin, 2002). The Romans not only used chestnuts as a year-round food, but also as an important tool associated with viticulture development, providing fences, vineyard stakes, poles, baskets, etc. (Bounous, 2005).

At present, the European chestnut stands, mainly located in the southern countries, derive from the Turkish Mediterranean gene pool (Villani *et al.*, 1994, 1999). Cultivated for centuries, the European chestnut became an important part of the cultural heritage in many rural areas of the continent. Historically, chestnuts were used as a staple food, providing a major food source for many European mountain populations (Bellini, 2005). Chestnut wood has also been used in house framing, furniture, tannin production, and as a source of renewable energy. Since the end of the 19th century, many chestnut stands have been degraded due to diseases, the depopulation of rural areas as consequence of industrial development, and the abandonment of cultural practices. However, over the last 20 years, and in line with the sustainable agriculture policies followed in many countries, the chestnut has been managed for both timber and nut production, to improve its conservation. A return to the massive consumption of the nut may be inconceivable, but European chestnut stands may play an important role in rural tourism, recreational areas, protection from erosion, landscape, etc., in addition to its original productive role.

1.2.1 Economic importance

1.2.1.1 Nut characteristics, production, and uses

The nut quality of European chestnuts is highly variable, depending on the individual varieties, which are the result of the natural selection that has been carried out for centuries through cultivation.

On average, the nuts have a content of 40–44% water, 49% carbohydrates, 5% proteins, and 1% fat, providing an excellent nutritional product. In each country, hundreds of varieties have been identified and most are used for local consumption; in France and Italy, the most important industrial nuts (some of which are European \times Asian hybrids) are derived from cultivars called “marrons”. Currently, one objective is the selection of the best cultivars from the germplasm available, which would be helpful in countries such as the United States, Chile, Australia, and New Zealand, where efforts are being aimed at selecting the superior types from European varieties that are best adapted to local conditions. The majority of European nut production comes from old groves, which, after important interventions, are being transformed into new plantations through rational grafting techniques (Bellini, 2005). In some cases, appropriate rootstocks (tolerance to diseases, good compatibility, adaptation to different pedoclimatic conditions) have been selected for young plantations (Bounous, 2002).

According to the data recorded in 2000 (Bounous, 2002), world nut production was around 473 000 metric tons (t) per year, of which 201 200 t (42%) were collected in Europe. Italy was the leading country, producing 78 400 t (88% of nuts and 12% of marron varieties) followed by Turkey (70 000 t), Spain and Portugal (20 000 t each), and France (12 600 t). Part of this production is for export (mainly to the United States), part is consumed unprocessed in traditional European uses, such as roasting or boiling, and only 20% of the production is used in the food industry. Produce is consumed seasonally because of the limited shelf life due to the high metabolic activity of the nuts, which, under storage, undergo water loss and fungal infections, affecting their quality (Sacchetti *et al.*, 2005). In the food industry, the nuts reach the market all year round as different commodities such as dried chestnuts, flour, marron glacés, creams, puré, pastes, peeled and frozen products, sweets, desserts, and even beer and liquors (Bounous, 2005).

1.2.1.2 Timber

European chestnut is a fast-growing tree species that displays a technologically and aesthetically

appreciated timber with great natural durability that can be used for high-value products. Most of the timber is obtained through traditional management systems (simple coppice) that do not always respond adequately to new market requirements that demand larger sized quality stems. Currently there is not as much demand for smaller logs. In some countries under the support of the European Union, new plantations producing medium- to large-sized logs can attain interesting profitability levels, around 125 Euros/m³ of wood, referring to trees with a diameter at breast height greater than 30 cm (Nunes *et al.*, 2005). Proper management of coppice stands is under study, taking into account factors such as rotation period, thinning, and final number of shoots per hectare (Patricio *et al.*, 2005).

1.2.1.3 Other products

The tannin content of the European chestnut varies from 1.8 to 12% (dry weight). Tannin extraction and purification was an important industrial activity between the 1850s and the 1950s, but even today countries such as Italy and France still maintain at least one company dedicated to this purpose (Robin, 2002; Zanuttini and Cielo, 2002). Chestnut culture provides additional associated products, among which honey, mushrooms, carbon, and cosmetics are the most important.

1.3 *C. dentata* (Marsh.) Borkh (American Chestnut)

The American chestnut is the largest chestnut species native to North America. Its original range covered most of the eastern United States and part of southern Canada (Little, 1977). Within its native range, and especially in the Appalachian Mountains, the American chestnut was often the dominant overstory species, often making up 25% to 50% of the stand (Jaynes, 1974). The preblight population size is at best a plausible guess, but numbers as high as 3.5 billion mature trees have been published (Anagnostakis, 1982; Roane *et al.*, 1986). Like the European chestnut, the American chestnut was used for timber, tannin, and nut production. In some regions, the nuts were so plentiful that domestic livestock was released into

the chestnut stands in the fall to forage (Rutter *et al.*, 1990).

The dominating force affecting the American chestnut throughout the 20th and the beginning of the 21st century was and is the chestnut blight. The fungus, *Cryphonectria parasitica* (Murr.) Barr., brought near-total destruction to the American chestnut as both a nut and timber crop (Hepting, 1974). Today, essentially no American chestnuts are harvested commercially and only a few cubic meters of lumber are sold annually. Although gone from the overstory, *C. dentata* is not extinct. The species still forms a significant component of the understory on many sites throughout its original range but it is extremely rare to see a large mature tree. In New York State, which is toward the northern limit of the original range, there are an estimated 4.2 million American chestnut trees 2.5–12.5 cm in diameter. But too few trees reach the 38 cm class to be recorded in the USDA (United States Department of Agriculture) Forest Service inventory (Alerich and Drake, 1995). The blight has reduced this once-dominant overstory species to an early succession stage shrub (Rutter *et al.*, 1990).

1.4 Traditional Breeding: Objectives, Tools and Strategies, and Achievements

European and American chestnuts have been the focus of attention by professional and amateur plant breeders, nurserymen, and pathologists for more than a century. They have been selected for various traits, moved from numerous points of origin, hybridized, and redistributed across the landscape. This comes after centuries of domestication by native people of both continents. The following is a brief exploration of the subject.

1.4.1 European chestnut breeding

The root rot or ink disease (caused by *Phytophthora* spp.) and chestnut blight (caused by *C. parasitica*) are the two most important diseases that affect European chestnut. Ink disease was first observed in Spain during the middle of the 19th century (Fernández de Ana, 2002), and the first breeding program to develop tolerant/resistant Euro-Japanese hybrids was initiated in Spain as

early as 1921 (Vieitez *et al.*, 1996). In France, a similar program was later developed, and a great number of first-generation hybrids have been selected—the rootstock for disease resistance and the cultivar for fruit quality. In the last years of the 20th century, an upsurge of ink disease occurred in various areas of Europe (Turchetti and Parrini, 1993; Abreu, 1996; Anselmi *et al.*, 1996), probably due to the winters being drier and warmer than usual, putting the trees under water stress during growth resumption the following spring (Turchetti and Maresi, 2005). Preliminary genetic studies suggest that at least two genes (which are incompletely dominant) seem to be responsible for resistance (Saleses *et al.*, 1993; Anagnostakis, 2001).

In Europe, chestnut blight was first detected close to Genoa (Italy) in 1938 and today it is still spreading in most European countries, except for Great Britain and some Northern countries (Vannini *et al.*, 2002). The mortality caused in both orchards and coppices is not as severe as in American chestnut stands, probably due to the higher natural tolerance of the European species, proper stand management, biological control of the disease, etc. The pioneering findings of Grente (1965, 1975, 1981) in Italy on the hypovirulence phenomenon allowed for the application of a biological control program against the disease (Heiniger and Rigling, 1994; Robin *et al.*, 2000; Anagnostakis, 2001). Hypovirulence is a virus-mediated attenuation of the pathogen virulence caused by *Cryphonectria hypovirus*, which accounts for the low severity of the disease. Although in some countries there is no proper disease management, there is a natural regulation of chestnut blight by spontaneous hypovirulence (Guérin and Robin, 2003). Consequently, the trees have coexisted with the disease for decades without there having been disastrous effects for the groves, although in countries such as Spain and Portugal, there has been continuous damage from the disease (Turchetti and Maresi, 2005). At present, conventional breeding programs aimed at identifying resistant individuals to ink and blight diseases are only underway in France (Ramos Guedes-Lafargue *et al.*, 2005) and Spain (Rodríguez *et al.*, 2005).

Large backcross breeding programs have not been, and probably will not be, carried out in Europe to obtain disease-resistant but nearly pure

European chestnut trees. By means of conventional breeding programs, a number of first-generation hybrids have been planted in different European countries. This in turn may have led to the loss of specific characteristics of *C. sativa*.

The chestnut population in Europe is highly complex due to its different expansion areas, selection of varieties, depletion caused by diseases, cultural abandonment, use of pure Asian species, and the spread of first-generation Euro–Asian hybrids resistant or tolerant to diseases. Many researchers in Europe are currently focusing their work on verifying the genetic variability of *C. sativa* in both natural populations and cultivated varieties, which will be of great relevance for the study and the conservation of biodiversity and adaptive potential. For these purposes, molecular markers are being used (Villani *et al.*, 1999; Casasoli *et al.*, 2001; Marioni *et al.*, 2003; Aravanopoulos *et al.*, 2005), which will help in the understanding of both short- and long-term evolution, in the studies of migratory routes, and in adaptive traits such as phenology, juvenile growth, and carbon isotope discrimination. The identification of quantitative trait loci will be an important tool for developing early selection methods.

1.4.2 American chestnut breeding

American chestnut breeding began in the 1800s. Originally, breeding objectives were to increase nut size in American chestnut by hybridizing it with European or Asian species, all of which produce larger nuts (Merkel, 1905; Van-Fleet, 1914; Jaynes, 1974; Anagnostakis, 1992). With the discovery of the chestnut blight in 1904 (Merkel, 1905) and the gradual realization of what a devastating problem it was becoming (Collins, 1912; Stoddard and Moss, 1913; Gravatt, 1924; Gravatt and Marshall, 1926; Zimmerman, 1926; Gravatt and Gill, 1930), focus shifted almost entirely to finding sources of blight resistance. Many strategies were considered. Blight-infested stands were searched for canker-free trees in hopes of finding naturally resistant American chestnut trees. Other chestnut species were imported and evaluated in field trials in hopes of finding a replacement species (Illick, 1921). Thousands of crosses were made between *C. dentata* and other chestnut species, with particular emphasis on *C. mollissima* and *C. crenata* in

hopes of transferring resistance into the American chestnut population (Graves, 1938; Graves, 1950; Berry, 1960; Diller *et al.*, 1964; Jaynes, 1964). By the 1960s, the various breeding programs had been curtailed or abandoned. Although differences in susceptibility were identified, no completely resistant pure *C. dentata* individuals had ever been located (Diller and Clapper, 1965; Jaynes, 1968). Hybrids between Chinese and American chestnut were intermediate in resistance, had lost considerable frost hardiness, and had acquired the spreading form typical of the Chinese chestnut parents used in the crosses (Burnham, 1988).

In the early 1980s, Charles R. Burnham, an emeritus corn cytogeneticist, and Philip A. Rutter, a previous Ph.D. student of evolutionary ecology, examined the literature on chestnut blight and chestnut breeding. After more than a year of collaboration, they decided that the American chestnut was a near-perfect candidate for the backcross breeding method (Burnham, 1981, 1990; Rutter and Burnham, 1982). It flowered early so that generations could be turned over relatively quickly for a tree species and the limited backcrossing that had been done in earlier breeding programs indicated that only a few major genes controlled resistance (Burnham, 1988). Burnham's reputation as a scholar was such that he was able to secure the serious attention of other plant scientists, and with their backing they formed a nonprofit organization, The American Chestnut Foundation (TACF), to carry out their backcross breeding program (Rutter and Burnham, 1982). Rutter began making controlled pollinations of chestnut in 1982. Over the next few years TACF acquired a property near Meadowview, Virginia, hired a staff with expertise in both the pathology of *C. parasitica* and chestnut breeding, acquired plant materials from the earlier breeding programs (Anagnostakis, 1992), and began backcrossing on a large scale.

Classical backcross breeding uses a single variety as a recurrent parent, usually a well-known variety with strong market acceptance and another, often a noncommercial variety or a related weedy species as the nonrecurrent parent. The two varieties are crossed and then rounds of backcrossing to the commercial variety and selection among the progeny for the trait of interest are carried out. The theoretical end result after six or more rounds of backcrossing and selecting followed by several generations of selfing, is that

99% of the genes are derived from the recurrent variety and the gene controlling the trait of interest has been transferred (Allard, 1960).

The modified backcross breeding strategy developed by TACF used Chinese chestnut as the nonrecurrent parent, but instead of using a single recurrent parent, they have been backcrossing onto a different set of American chestnut parents for each generation. The last backcross will be carried out by each of the state chapters of the Foundation onto locally selected parent trees. Rather than selfing to achieve homozygosity of the blight resistance genes, the backcross populations will be intercrossed. The end result is intended to be a blight-resistant but highly genetically diverse set of regionally adapted chestnut populations deriving approximately 93% of its genes from *C. dentata* (Hebard, 1992). Diskin *et al.* (2006) reported that a sample of the third backcross generation strongly resembled the American chestnut seedlings in a composite score of leaf and twig characters, indicating that the American chestnut phenotype will be recovered.

C. dentata flowers early for a tree species; therefore, only 3 to 5 years are needed per generation. As of 2007, TACF had carried out three generations of backcrossing, followed by one of intercrossing. The resulting progeny, designated BC₃F₂ are being evaluated for blight resistance (Hebard, 2006).

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

The modified backcross breeding program being carried out by TACF is a skillful adaptation of a thoroughly proven plant breeding technique. Using molecular markers and linkage mapping Kubisiak *et al.* (1997) found that two or possibly three major loci control blight resistance, well within the capabilities of the backcrossing method. There are, however, some fundamental limitations to backcross breeding or other traditional tree breeding approaches.

1.5.1 Precision of gene transfer

Both backcross breeding and genetic engineering are methods of transferring a small number of

genes from one species or variety to another. They differ in the degree of precision of the transfer process. Backcrossing begins with the hybridization of the two parents. This transfers one copy of each gene from both parents into the hybrid progeny. Elimination of genes from the nonrecurrent parent depends on the processes of dilution and selection. After three backcross generations, independent assortment predicts that a population will contain, on average, approximately 7% of the genome of the nonrecurrent parent. Assuming that the *Castanea* genome contains 25 000 genes, roughly the same number as in *Arabidopsis thaliana* (The *Arabidopsis* Genome Initiative, 2000), 7% would be approximately 1700 genes. *C. dentata* and *C. mollissima* diverged from a common ancestor roughly 42 million years ago, so they share many identical alleles. According to Lang *et al.* (2006), the sequence divergence among *Castanea* species is roughly 1% (range among species was 0–2.4%). The backcrossing method will, therefore, leave behind the equivalent of 17 Chinese chestnut genes at random locations and with unknown functions. In practice, genes are arranged in linkage groups that segregate together until separated by crossover events. Often these crossover events occur at some distance from the gene(s) of interest. When this happens, selection for the trait of interest transfers several to many linked genes. This phenomenon is called linkage drag (Young and Tanksley, 1989). Backcross breeding, therefore, introduces approximately 17 random genes and an unknown number of linked genes of unknown function. These traces of the nonrecurrent *C. mollissima* parent genome are probably harmless; however, their existence should be recognized as a fundamental characteristic of backcrossing.

Agrobacterium-mediated transformation decreases in efficiency as the size of the transfer DNA (T-DNA) region increases; therefore, molecular biologists package the genes they want transferred as tightly as possible. The construct used to transform *C. dentata* contained approximately 6 kb of DNA and three well-characterized genes (described elsewhere). One of the ironies in the debate over genetic engineering is that critics often raise the argument about “unknown genetic effects”, while it is actually conventional breeding that introduces a greater degree of genetic uncertainty.

1.5.2 Relative speed with which new genes can be transferred

Development of transformation systems for both *C. dentata* and *C. sativa* has taken approximately two decades (Maynard *et al.*, 1998). This is roughly the same amount of time it has taken TACF to reach the BC₃F₂ generation. However, now that transformation systems are in place, the time required to transfer a new set of genes into chestnut somatic cell lines and regenerate acclimatized somatic seedlings ready for blight screening could be as little as 2 years. With backcrossing, there are two fundamental limitations: how quickly trees can be induced to flower and how quickly the resulting progeny can be scored for blight resistance each generation. Both of these steps have been reduced, but they are unlikely to be reduced much further. Therefore, if a new blight resistance allele were discovered in another chestnut species, it would require an additional 15–20 years to make the new cross and again reach the BC₃F₂ generation.

2. DEVELOPMENT OF TRANSGENIC CHESTNUTS

2.1 European Chestnut Transformation and Regeneration

2.1.1 Genetic transformation through organogenesis

The first attempts to transform European chestnut made use of both hypocotyl segments from *in vitro* germinated seedlings and stem segments of *in vitro* grown shoots, which were co-cultured with *Agrobacterium tumefaciens* (Seabra and Pais, 1998, 1999). In the two experiments, the transformation efficiency ranged from 1% to 2%, whereas the percentage of escapes (shoots developed in media with high concentration of kanamycin but with no *nptII* (neomycin phosphotransferase II) integration) reached 97%. Integration of the genes was transient as after 1 year of *in vitro* culture maintenance, the transgenic character of the cultured shoots was lost (R. Seabra, personal communication).

Plant regeneration systems based on adventitious bud induction have not proved reliable in

European chestnut (San-José *et al.*, 1984; Seabra and Pais, 1999). However, the use of meristematic tissue from apical or axillary buds as a target tissue for genetic transformation is of increasing interest for species identified as recalcitrant for somatic embryogenesis and/or adventitious shoot regeneration (Paz *et al.*, 2004; Petri and Burgos, 2005). The pre-existing meristems should be stimulated to proliferate by complete or incomplete tissue disorganization or dedifferentiation followed by regeneration of multiple shoots. We have investigated the shoot production response of “preconditioned” cotyledonary node explants cultured for 4 weeks on media supplemented with thidiazuron (TDZ). These explants showed an altered meristematic axillary region, with cell proliferation giving rise to expanded meristems, which, upon TDZ shoot-induction treatment, efficiently produced multiple shoot buds with no intervening callus phase (San-José *et al.*, 2001). The ability of this “target meristematic tissue” to form multiple shoots suggests that chestnut cotyledonary nodes are still promising explants for the production of transgenic plants.

Genetic transformation experiments were carried out on European chestnut by co-culturing cotyledonary node explants with *A. tumefaciens* harboring reporter genes (Corredoira *et al.*, 2005). The influence of preconditioned medium, the strain/plasmid combination, and the co-culture period were assayed. Following 12 weeks of successive subcultures in TDZ- and benzyladenine-containing media (4 and 8 weeks, respectively), 2.3% of the explants developed kanamycin-resistant shoots. Although this transformation system needs to be optimized and transgenic chestnut plants have yet to be obtained, the use of the “stimulated” organogenic pathway would be an interesting alternative to the embryogenic regeneration system.

2.1.2 Genetic transformation through somatic embryogenesis

The use of somatic embryos and embryogenic tissue as the target material for genetic transformation has resulted in important breakthroughs in the genetic engineering of trees, as somatic embryos contain a large proportion of dividing cells and have the potential to regenerate complete plants.

In European chestnut, somatic embryogenic cultures have been induced from immature zygotic embryos (Vieitez *et al.*, 1990; Vieitez, 1995; Sauer and Wilhelm, 2005; Corredoira *et al.*, 2006) and from leaf sections of *in vitro* cultured shoots (Corredoira *et al.*, 2003). Embryo proliferation by secondary embryogenesis and moderate rates of germination and plant recovery were also reported (Corredoira *et al.*, 2006). Making use of these embryogenic cultures, an efficient genetic transformation protocol for *C. sativa* has been described for the first time (Corredoira *et al.*, 2004) by means of the co-culture of somatic embryos with different strains of *A. tumefaciens* carrying marker genes. Small clumps (4–7 mg) of two to three somatic embryos in the globular or heart stages that were isolated from embryogenic cultures and maintained by secondary embryogenesis were used. The *Agrobacterium* strains C58C1pMP90 and EHA105 were used for transformation experiments. Strain C58C1 carries a pBI121 plasmid containing an *nptII* marker gene driven by the *nos* (nopaline synthase) promoter for kanamycin selection and the β -glucuronidase (*gus*) reporter *uidA* (β -glucuronidase) gene, driven by the cauliflower mosaic virus (CaMV) 35S promoter. Strain EHA105, carrying either a pUbiGUSINT or a p35SGUSINT plasmid, was also used; these binary vectors contain the *nptII* gene driven by the *nos* promoter and the *uidA* reporter gene (*gus*) driven by either the maize (*Zea mays* spp.) ubiquitin (*Ubi-1*) or the CaMV 35S promoter. Somatic embryo clumps were immersed in the bacterial suspension, blot-dried on sterile filter paper, and transferred to embryo-proliferation medium. Following different periods of co-culture (3 or 4 days), the embryos were washed with sterilized distilled water containing 500 mg l⁻¹ cefotaxime, and were transferred to fresh proliferation medium supplemented with 300 mg l⁻¹ carbenicillin, 200 mg l⁻¹ cefotaxime, and 150 mg l⁻¹ kanamycin (selection medium). After 12 weeks of culture, with subcultures to fresh selection medium at 15-day intervals, surviving explants that developed somatic embryos were evaluated on the basis of GUS activity to determine the transformation efficiency, defined as the percentage of initial explants that developed GUS-positive embryogenic cultures (Figure 1). Cotyledonary-stage regenerated embryos were isolated from GUS-positive lines and subcultured

Figure 1 Genetic transformation of European chestnut: (a) kanamycin-resistant somatic embryos after 12 weeks on selection medium; (b) histochemical GUS analysis of somatic embryos transformed with *Agrobacterium tumefaciens* strain/plasmid combination EHA105/p35SGUSINT

on selection medium to proliferate and to establish embryogenic transgenic lines. In order to confirm the presence of the *nptII* and the *uidA* genes in GUS-positive embryogenic lines, polymerase chain reaction (PCR) and Southern blot techniques were used (Corredoira *et al.*, 2004).

2.1.3 Regeneration of whole plants

In general, it has been observed in European chestnut that the conversion rate of transformed embryos is lower than that obtained in the corresponding untransformed line. Transformed embryos were germinated according to Corredoira *et al.* (2003) with the germination medium supple-

mented with 75 mg l^{-1} kanamycin. Although low plantlet conversion rates (6.3–11%) were recorded, shoots from germinating embryos with shoot development only were successfully multiplied by axillary shoot proliferation, which allows the production of unlimited number of transgenic shoots to be rooted. Rooting frequencies higher than 50% were obtained for shoots derived from different transgenic embryogenic lines. This constitutes a valuable alternative for plant regeneration from transformed germinating embryos in which plantlet conversion is not achieved. Transgenic chestnut plants were acclimatized in phytotron and grown in the greenhouse. The presence of transferred genes in leaves from these plants was also verified by the GUS assay and PCR analysis (Figure 2).

Figure 2 (a) Transgenic plantlet originated by the rooting of a shoot developed from a transformed embryo; (b) histochemical GUS analysis of a leaf excised from a transformed plant

2.1.4 Optimization experiments

In order to improve the protocol for genetic transformation of European chestnut a number of parameters were evaluated.

In the first experiment, the effect of bacterial strain/plasmid combination (EHA105/pUBIGUSINT, EHA105/p35SGUSINT, and C58C1/pBI121) and the length of the co-cultivation period (3 or 4 days) were investigated. The transformation efficiency was clearly related to the strain/plasmid combination used. The highest transformation frequency (25%) was achieved when the explants were co-cultured for 4 days with the strain/plasmid combination of EHA105/pUBIGUSINT. Four days of co-culture was a more effective period than 3 days although significant differences were only observed with the strain EHA105/pUBIGUSINT. The selection efficiency (defined as the percentage of kanamycin-resistant explants that developed GUS-positive embryogenic cultures) was relatively high (71.4%). This indicates that the kanamycin concentration (150 mg l^{-1}) in the selection medium and the subculture regime during 12 weeks appears to be an efficient selection system. Amplification of specific primers to the *nptII* and *gus* genes was detected in all of the GUS-positive transgenic lines analyzed (Corredoira *et al.*, 2004).

To investigate the effect of paramomycin as another potential selection agent, various concentrations ($25\text{--}200 \text{ mg l}^{-1}$) of this antibiotic were assayed and 150 mg l^{-1} of paramomycin was found to inhibit the growth of somatic embryos. Subsequently, somatic embryos of two embryogenic lines, one with high transformation capacity and other with low transformation capacity, were transformed with the strain EHA105/pUBIGUSINT and were cultured on selection medium with 150 mg l^{-1} of either kanamycin or paramomycin. The transformation efficiency was higher in both lines: 30% and 8% for kanamycin versus 13.3% and 1.7% for paramomycin. These results suggest that kanamycin is more efficient than paramomycin for selection of transgenic somatic embryos in European chestnut.

Acetosyringone, when added to various stages during the transformation process, has been shown to enhance transformation efficiency in some species (Wenck *et al.*, 1999; Lopez *et al.*, 2004).

However, when acetosyringone was applied to the bacterial suspension culture overnight and during the co-culture period, it was significantly detrimental in the two concentrations (100 and $200 \mu\text{M}$) evaluated (Corredoira *et al.*, 2004). The temperature during the co-culture period and the effect of wounding of the somatic embryos have also been analyzed. The temperature regime did not significantly affect the transformation efficiency, which ranged from 23.3% (at 28°C) to 28% (at 25°C). Neither was there a significant increase in the transformation capacity when somatic embryos were wounded by pricking them with a hypodermic needle, although higher values were scored using unwounded material.

To determine the effect of bacterial density on the transformation frequency, chestnut somatic embryos were inoculated with *Agrobacterium* suspensions of different optical density (OD) values (0.3, 0.6, and 0.9 at 600 nm). Transformation efficiency was highest when somatic embryos were infected with the bacterial culture in the exponential phase of growth ($\text{OD}_{600} = 0.6$) (Corredoira *et al.*, 2005).

Different developmental stages of chestnut somatic embryos, including isolated globular embryos, small embryo clumps (2–3 embryos at globular or heart stages), and isolated cotyledonary embryos, were used to assess the effect of the explant type used as target material on transformation. The transformation efficiency obtained with isolated globular embryos and embryo clumps (30.0% in both explant types) was significantly higher than that obtained with cotyledonary embryos (6.7%). The low transformation frequency of this type of explant might be related to its lower proliferation capacity through secondary embryogenesis, in comparison to the other explants. In addition, the genotype of the embryogenic line also had a remarkable influence on the transformation capacity of European chestnut. Of the six embryogenic lines evaluated, lines C12-H1 and C13-F1 produced higher transformation frequencies (21% and 33.3%, respectively) than lines CI-1, CI-3, CI-6, and C785L-1, with values of 3.3, 5.0, 1.7, and 10.0%, respectively.

To facilitate the management of the transformed embryogenic lines, a protocol for the long-term storage of this germplasm should be defined. Three European chestnut transgenic cell lines

were successfully cryopreserved using a single vitrification procedure, with embryo recovery frequencies ranging from 52% to 65%. The stable integration of the *uidA* gene into the transgenic plants that were regenerated subsequent to cryopreservation was confirmed (Corredoira *et al.*, 2007).

In conclusion, a reliable protocol for genetic transformation of European chestnut with marker genes has been defined. It should also be noted that the expression of the inserted transgenes has remained stable for 3 years in both somatic cell lines and regenerated plants.

Attempts to transform European chestnut with genes of interest are in progress. In this respect, García-Casado *et al.* (2000) have purified a thaumatinlike protein (CsTL1) from mature cotyledons of European chestnut; they have also demonstrated that the isolating protein has antifungal activity *in vitro*. The overexpression of this gene in chestnut would increase the tolerance or resistance to the diseases. The 1 kb CsTL1 complementary DNA (cDNA) (provided by Dr. Allona, ETSI Montes, UP Madrid, Spain) was used to perform a PCR reaction with specific CsTL1 primers (5'-GAGCTCGGGTAACC-3' and 5'-GTGGATCCCCCGGG-3'). Each primer carried a restriction endonuclease site (*Bam*HI and *Sac*I, respectively) to allow directional cloning of the PCR product. In order to obtain the gene sequence of the CsTL1, the PCR product was digested with *Bam*HI and *Sac*I and the resulting fragment was purified on an agarose gel. This fragment was subcloned into the *Bam*HI and *Sac*I cloning sites of the binary vector pBI121

(Clontech, Palo Alto, California, USA), replacing the preexisting *uidA* gene. The resulting vector was designated p35SCsTL1 and transferred into the *A. tumefaciens* disarmed strain C58C1 using the freeze and thaw method (Holsters *et al.*, 1978). The recombinant bacteria were selected on Luria broth (LB) medium containing 50 mg l⁻¹ kanamycin, 25 mg l⁻¹ gentamicin, and 20 mg l⁻¹ rifampicin.

2.2 American Chestnut Transformation and Regeneration

2.2.1 *Agrobacterium* strain and transgenes

The American chestnut somatic embryo cell lines described by Polin *et al.* (2006) were transformed using *A. tumefaciens* strain EHA105 containing the plasmid construct pΔVspB-OxO, which included a germinlike *oxalate oxidase* gene (*OxO*) (Dratewka-Kos *et al.*, 1989) to enhance blight resistance, a phosphinothricin acetyltransferase gene (*bar*) as a selectable marker, and a green fluorescent protein gene (*mgfp5-ER*) (Haseloff and Siemering, 1998) as a visual marker (Figure 3). The putative blight-resistance-enhancing gene, *OxO*, is from wheat (*Triticum aestivum*). It is driven by the promoter region of a soybean (*Glycine max* (L.) Merr.) vegetative storage protein (VspB4) (Mason *et al.*, 1993) and has an *Act2* (rice actin-2) terminator derived from the *actin-2* gene of *A. thaliana*. The VspB promoter was found to have a 726-bp deletion that reduced *OxO* expression and thus the gene construct originally named pVspB-OxO was renamed pΔVspB-OxO. (For a

Figure 3 Genetic transformation of American chestnut: (a) PPT-resistant somatic embryos viewed under white light; (b) same somatic embryo cluster viewed under UV light showing embryos expressing GFP

full description of the *OxO* gene and the VspB promoter, see Section 3.5.2) The selectable marker gene, *bar*, is from *Streptomyces hygroscopicus* and has a Ubi-3 promoter and terminator from the ubiquitin-ribosomal protein gene (*ubi3*) in potato (*Solanum tuberosum* L.) (Garbino and Belknap, 1994). The *bar* gene confers tolerance to herbicides containing phosphinothricin (PPT), such as Finale[®], and was not only included in the vector as a selectable marker but is also intended to be used as a gene of interest in nursery management of the transgenic seedlings in subsequent breeding program. The screenable marker, *mgfp5-ER*, is from *Aequorea victoria* and has a CaMV 35S promoter from the cauliflower mosaic virus and a nos 3' terminator from the T-DNA region of *A. tumefaciens*. The *mgfp5-ER* gene has been extensively modified to improve expression in plants. It has had a cryptic intron removed, is targeted to the endoplasmic reticulum, has improved thermotolerance, and has modified spectral properties so that it can be excited at either 400 nm or 470 nm (Siemering *et al.*, 1996; Mankin and Thompson, 2001).

Andrade *et al.* (2005, 2006) used the *A. tumefaciens* strain AGL1, harboring the plasmid pCambia 2301 (carrying the *nptII* selectable marker and *uidA* reporter gene) to transform American chestnut embryogenic cultures, from which transgenic somatic seedlings were later regenerated.

2.2.2 Genetic transformation through organogenesis

Research to develop a transformation system for American chestnut followed a remarkably similar path to that described for European chestnut (Sections 2.1.1 through 2.1.4). Initial research focused on transforming leaf discs. Although a few transgenic calli were produced, no transgenic shoots were ever recovered (Maynard, 1991a). Attempts to transform and regenerate shoots from the meristematic regions of shoot tips were similarly unsuccessful (Maynard, 1991b). Small pilot studies with cotyledons and embryos excised from mature nuts were also carried out with little success. Occasionally, a callus cell line expressing the marker genes was produced; however, no

cell lines were ever identified that were both organogenic and transgenic (Maynard, 1991a).

2.2.3 Genetic transformation through somatic embryogenesis

The first reports of transgenic American chestnut tissues (as opposed to undifferentiated callus) were by Carraway *et al.* (1994) who used micro-projectile bombardment (biolistics) to transform proembryogenic masses derived from immature zygotic embryos. Once attention was focused on embryogenic cultures as the target tissue of choice for transformation, a number of variations were tested and progress was relatively rapid (Merkle, 1994; Carraway and Merkle, 1997; Merkle and Dean, 2000; Polin *et al.*, 2006).

Both biolistic and *Agrobacterium*-mediated transformation were evaluated. In a series of gene gun (Helios Gene Gun, Bio-Rad Laboratories, Hercules, California, USA) experiments, optimizing gas pressure, particle size, and a 4-h prebombardment treatment in a high osmotic potential medium, improved the transient expression manyfold, however, no stable transformation events were recovered (Polin, 2004).

As of March 2007, the US Department of Agriculture electronic database, AGRICOLA, contained more than 3200 citations for "*Agrobacterium* transformation". Researchers are frequently reporting modifications to the basic technique as they attempt to insert genes into new plant species. One such modification, described as a desiccation step, was first reported for wheat by Cheng *et al.* (2003). Desiccation was key to transforming American chestnut somatic embryos and keeping them embryogenic (Polin *et al.*, 2006). In the desiccation procedure, after 1 h of inoculation with *Agrobacterium*, the somatic embryos were transferred to a Petri dish containing a slightly moistened sterile filter paper, but lacking the traditional semisolid tissue culture medium. The embryo clumps were placed in small stacks (approximately 5 mm in size) on the filter paper. The Petri dishes were wrapped with cling film and co-cultivated in the dark at room temperature for 2–3 days. The postdesiccation steps followed standard *Agrobacterium* transformation protocols. Embryos were transferred to an *Agrobacterium*-lethal medium containing carbenicillin and

cefotaxime for a week and then transferred to a selection medium containing the same antibiotics plus PPT to eliminate any nontransformed plant cells. Putative transformants were transferred to fresh selection medium every 2 weeks. Over a period of 2–6 months, vigorously growing embryo clusters that showed uniform green fluorescent protein (GFP) fluorescence under a Nikon Stereoscopic Zoom Microscope SMZ1500 with an En GFPLP 83458M filter (Nikon Instruments, Inc., Melville, New York, USA) were selected as putative transformation events. Confirmation of transformation was done with Southern hybridization analysis (Polin *et al.*, 2006).

To increase the rate of transformation, several modifications to the basic desiccation procedure were tried. Acetosyringone had a positive effect when added to the *Agrobacterium* inoculum in a virulence-induction step, but as was observed for European chestnut, it had no effect or a slightly negative effect when added to the co-cultivation medium (Rothrock, 2006). Rothrock *et al.* (2007) found that wounding the embryos by any of several methods (vortexing with fine sand, vacuum infiltration, or sonication) had no effect or had a negative effect on transformation frequency. Wounding also induced a higher proportion of callus rather than additional embryos. The two clones tested gave slightly different results. For one clone that multiplied as tiny loosely aggregated embryos, the best treatment among those examined was to simply add the *Agrobacterium* inoculum to the Petri dish containing intact and undisturbed somatic embryos. The method was named “plate flooding” (Rothrock *et al.*, 2007). For the second clone that multiplied as relatively large well-aggregated embryos, the desiccation method and plate flooding gave similar results and both were superior to the wounding treatments.

2.2.4 Regeneration of whole plants: three alternatives

After stable transgenic somatic embryo cell lines have been identified, it is necessary to regenerate them into whole plants. At least three alternatives exist. Somatic embryos can be induced to germinate and grow into somatic seedlings (Robichaud *et al.*, 2004; Andrade and Merkle, 2005), somatic embryos can be induced

to produce shoots and those shoots multiplied, rooted, and acclimatized (Xing *et al.*, 1997, 1999; Polin *et al.*, 2006), or those clones that are recalcitrant to rooting treatments can be inserted into germinating nuts, a process called nutgrafting (McGuigan, 2007).

2.2.4.1 Somatic embryo/somatic seedling

Somatic embryo/seedling (SE/SS) technology has been promoted as the approach holding the most promise for operational *in vitro* mass propagation of elite genotypes (including transgenics) of a number of forest tree species (e.g., Gupta *et al.*, 1993; Merkle and Trigiano, 1994). Commercially important conifers, in particular, have been targeted for propagation via somatic embryogenesis and this approach is now at the point of commercialization for some top commercial pine species (Sutton, 2002; Nehra *et al.*, 2005). Somatic embryogenesis may ultimately provide the most efficient route for mass propagation of blight-resistant American chestnut as well, whether the blight resistance is conferred by transgenes or by conventional breeding. Following the first report of somatic embryogenesis in American chestnut (Merkle *et al.*, 1991), progress on germination and conversion of the somatic embryos was slow. Carraway and Merkle (1997) produced a few somatic seedlings, but these failed to survive transfer to *ex vitro* conditions. Through a combination of embryogenesis and micropropagation, Xing *et al.* (1999) established American chestnut plantlets in the field. Robichaud *et al.* (2004) produced the first field-plantable American chestnut somatic seedlings by supplementing the medium during embryo development and maturation with asparagine and/or glutamine. However, germination rates were still low, averaging 9%, and conversion frequencies were even lower, averaging 0.4%.

From approximately 2004 through 2006, American chestnut somatic seedling production efficiency was increased by over two orders of magnitude following testing of additional treatments that positively affected both germination and conversion. One major advance was the use of embryogenic suspension cultures, which could be size fractionated on stainless steel screens and plated on nylon mesh overlaid on semisolid

basal medium. This allowed for the production of relatively synchronous, singularized embryos, rather than clusters of fused embryos (Andrade and Merkle, 2005). By applying 12 weeks of cold stratification at 4 °C to these embryos, conversion frequency for one American chestnut line rose to 47%, and by combining cold treatment and activated charcoal in the germination medium, germination and conversion of embryos of another line were boosted to 77% and 59%, respectively (Andrade and Merkle, 2005). Preliminary data indicate that further increases in somatic seedling production efficiency may be possible for some genotypes by applying even longer cold stratification treatments and light quality treatments during germination (Johnson *et al.*, 2007). Hundreds of American chestnut somatic seedlings derived from these cultures have now been acclimatized and grown in the greenhouse. A subsample of these somatic seedlings grown in a Georgia nursery following a year in the greenhouse reached heights of up to 1.5 m following their first season of growth (Johnson *et al.*, 2007). While additional improvements are needed to make SE/SS technology useful for mass propagation of blight-resistant American chestnuts, the results are promising. As is proving to be the case with pine somatic seedlings, a robust SE/SS system for American chestnut should provide a number of advantages over micropropagation, including higher multiplication rates and the potential for scale-up and delivery via bioreactor and synthetic seed technologies, reducing labor costs (Merkle and Dean, 2000).

2.2.4.2 Germination/micropropagation

Not all American chestnut somatic embryo cell lines are able to germinate into seedlings. Some need to produce shoots first, and then those shoots multiplied, rooted, and acclimatized. Polin *et al.* (2006) observed significant differences among six cell lines tested in transformation efficiency, ease of regeneration of shoots, ease of rooting, and in production of whole plants. In pilot studies, more than a dozen cell lines derived from different trees were evaluated to identify two or three that could be reliably transformed, regenerated into shoots, rooted and finally, acclimatized (Polin *et al.*, 2006). For some somatic cell lines that were difficult or impossible to germinate, it was possible to regenerate whole plants if even a single embryo could be induced to regenerate a shoot (Polin *et al.*, 2006).

Once rooted (Figure 4), the plantlets were potted in a 2:1:1 peat moss:vermiculite:perlite mix. Clear-plastic Magenta GA-7 vessels were inverted over each plant to provide 95% or higher relative humidity, similar to what the plants had been exposed to *in vitro*. The plants were placed in a growth chamber for acclimatization. As the plantlets grew and began to develop new leaves, the lids were removed in stages, first lifting them 1 cm for an hour at a time, then to 1 cm for a day, followed by removing them completely for an hour and finally removing them completely for a full day. If at any point during the acclimatization period the plant began to wilt, the lid was replaced until the plant either recovered (at which point the

Figure 4 Rooting of transgenic American chestnut: (a) roots formed on transgenic chestnut shoots viewed under white light; (b) same roots viewed under UV light showing GFP expression

process was repeated) or the plant died. After the plants became accustomed to the growth chamber conditions, they were moved into a greenhouse (first for 1 h a day than for 2 h a day and so on until they were adjusted to the drier, high-light conditions) (LaPierre, 2003; Maynard *et al.*, 2006).

2.2.4.3 Nutgrafting

As described by Polin *et al.* (2006) for American chestnut, some cell lines will readily multiply as shoot cultures but those shoots fail to root. Nutgrafting (or nurse-seed grafting) is an alternative to *in vitro* rooting. Moore (1963) was the first to describe propagation of American chestnut by nutgrafting. He used one- or two-bud hardwood scions inserted into a slit made between the two cotyledons of germinated chestnuts. We are attempting to adapt the technique for use with scions grown *in vitro*. In a modified procedure taken from Greenwell (2002) and Schibig (2003), the roots of germinating chestnuts were severed from the cotyledons and a wedge-shaped cut was made at the base of each tissue cultured shoot. The shoot was then inserted into a slit cut in the cotyledons. The graft was placed in a Magenta GA-7 vessel filled with moistened sphagnum moss. Two nutgrafts were successful out of approximately 40 attempts using transgenic American chestnut shoots (McGuigan, 2007).

2.3 Testing Transgenic Chestnuts for Blight Resistance

2.3.1 Greenhouse screening for blight resistance

Traditionally, blight resistance is measured on trees that are 3 years old or older using a cork-borer inoculation method (Griffin *et al.*, 1983). Powell *et al.* (2007) developed a technique that can differentiate resistant Chinese chestnut from susceptible American chestnut using seedling stems that are only 3–4 mm in diameter (Figure 5). This technique will be used as an early indication of enhanced blight resistance. All transgenic events will be inoculated with two virulent strains of *C. parasitica*, EP155 and EP42, to ensure the results are not due to a particular strain of the pathogen. Chinese and American chestnut seedlings will be used as positive and negative controls, respectively. In pilot studies, susceptible plants were girdled by a canker in approximately 4 weeks, while resistant plants formed callus in the wounds and survived (Powell *et al.*, 2007).

2.3.2 Field testing of transgenic American chestnut trees

In the spring of 2006, two transgenic American chestnuts were planted in the field in Syracuse, New York (Figure 6). Two more were planted in the fall of 2006. The four plants were all from

Figure 5 Example of a chestnut seedling resistance assay: (a) killing canker on susceptible American chestnut; (b) healing canker on resistant Chinese chestnut; (c) inoculated American chestnut seedlings on left showing wilting tops and inoculated Chinese chestnut seedlings on right surviving

Figure 6 The first two transgenic American chestnuts were planted in the field June 7, 2006 in Syracuse, NY, USA derived from somatic cell line WB275-27, transformation event LP 28 and given the variety name “Wirsig”

the same parent clone (WB275-27 obtained from H. Dayton Wilde at MeadWestvaco Corporation, Summerville, South Carolina, USA) and the same transformation event (LP 28). This transformation event was given the variety name “Wirsig” in honor of Arlene and Stan Wirsig, two of the original members of the New York State Chapter of the American Chestnut Foundation. One tree from the spring planting died soon after planting, but the second tree grew a new shoot approximately 45 cm high. By late October, it had set apparently normal resting buds and dropped its leaves. One tree from the fall planting was accidentally destroyed. The second set bud soon after planting. It appeared to enter dormancy normally in the fall, but did not survive the winter, possibly due to its small size at planting. A third planting of approximately 15 trees is planned for the spring of 2007.

2.4 Specific Regulatory Measures Adopted

All recombinant-DNA research described in this review has been carried out in laboratories certified by their respective Institutional Biosafety Committees. The 2006 field trial of American chestnut was initiated after submitting a Release Notification and receiving acknowledgement (No. 06-090-21n) from the USDA, Animal and Plant Health Inspection Service, Biotechnology Regulatory Services (APHIS, BRS).

3. FUTURE ROAD MAP

3.1 Expected Products

For American chestnut, the primary improvement objective is simple—blight resistance. This could

be broadened to enhancing resistance to other important chestnut pathogens. At least initially, no attempt will be made to enhance nut size, reduce flowering age, or to improve any of the other traits that might be of interest to the horticulture industry. The European chestnut and the Chinese chestnut have almost entirely supplanted the American chestnut for human consumption in North America. It is unlikely that this market will be recaptured in the near future.

One approach to breeding for durable disease resistance is to incorporate multiple pathogen resistance-enhancing genes. This approach, called “gene stacking” or “gene pyramiding”, holds great promise for long-lived tree species like the American chestnut. One desirable feature for stacking genes is to use genes that enhance resistance by different mechanisms so that single mutations in the pathogen will not overcome both transgenes simultaneously. Then the hypothetical probability of the pathogen acquiring mutations to overcome the enhanced resistance is the product of the probabilities of overcoming each transgene individually, which is increasing small as the number of stacked genes increase. Ideally these stacked genes should be as closely linked as possible, so that in subsequent generations the genes segregate together. A multiple gene construct containing a *Trichoderma harzianum* endochitinase, Ech42 (Lorito 1998; Lorito *et al.*, 1998), a TEV-NIa self-cleaving proteinase (Bodman *et al.*, 1995; Carrington and Dougherty, 1988; Ceriani *et al.*, 1998; Dasgupta *et al.*, 1998) and a wheat oxalate oxidase (Lane, 2002), in which one large coding region was driven by a single promoter was developed by W.A. Powell, H. Gao and H. Liang (Liang *et al.*, 2005). The large peptide string is then cleaved by the NIa proteinase into active Ech42 and OxO enzymes. This construct has been shown to cleave properly in *Arabidopsis* and retain expected enzymatic activity (Liang *et al.*, 2005). Similar constructs with constitutive and wound-inducible promoters are currently being used to transform American chestnut. Future constructs could combine any combination of gene products, including possible combinations of antimicrobial peptides (Powell *et al.*, 1995, 2000; Liang *et al.*, 2002) or other available resistance-enhancing polypeptides and enzymes (Powell *et al.*, 2006).

3.2 Public Perceptions

European chestnut is used for both wood products and as an edible nut crop with the latter use probably dominating. Although a blight-resistant European chestnut would be welcomed by many nurserymen and orchardists, a combination of public acceptance concerns, regulatory roadblocks and reasonably successful alternative techniques to control the blight in commercial orchards will probably keep transgenic European chestnut trees confined to the laboratory and greenhouse for the immediate future.

The situation is different for the American chestnut. Over the last decade C. Maynard, W. Powell and S. Merkle have presented “The American Chestnut Story”, which includes information on using genetic engineering to achieve blight resistance, to dozens of groups ranging from the African Violet Society to the national convention of the Society of American Foresters. Reactions have been almost universally positive. Public acceptance for genetically modified crops in general is higher in the United States than in Europe (Lusk and Rozan, 2005; Byrne, 2006). But what we have observed for blight-resistant American chestnut goes well beyond acceptance and might be better described as eager anticipation. The typical question asked of us has been how soon will they be available.

3.3 Deployment of Blight-Resistant American Chestnuts

3.3.1 Clonal deployment: micropropagation, nutgrafting and somatic seedlings

As discussed in Sections 2.2.4.2 and 2.2.4.3, micropropagation and nutgrafting will allow clones that are recalcitrant to somatic seedling production to be regenerated into whole plants. The primary disadvantage of both micropropagation and nutgrafting is the high labor inputs and, therefore, high production costs. Both of these propagation tools may be used to produce limited numbers of expensive plants. They may be marketed through the horticulture industry as street trees, but costs will probably be prohibitive for commercial reforestation. They may also be

of use as planting stock for seed orchards to be described in Section 3.2.2.

Somatic embryo or somatic seedling technology will provide the most efficient route for mass propagation of blight-resistant American chestnut for commercial reforestation if further improvements can be made in germination and conversion rates, and the process can be scaled up. Production costs are speculative, but they will be considerably lower than micropropagated plants or nutgrafts, but probably higher than bare-root seedlings.

3.3.2 Seedling deployment: producing a blight-resistant and genetically variable population

Chestnut trees flower early, but may take a decade or longer before they reach sufficient size to produce large crops of nuts. Seed orchards must, therefore, be considered a long-term delivery method. Seedlings do, however, have two advantages over the clonal propagation methods described in Section 3.2.1. They are usually less expensive to produce than any of the clonal propagation methods, and if the transgenic plant can be crossed with wild-type trees and still express resistance, the resulting population can contain considerable genetic diversity. In annual crop species, the problem of introducing genetic diversity is dealt with by using a transgenic line as the nonrecurrent parent in a backcross breeding program (Mumm and Walters, 2001). In cotton, it can take as little as five years to move a transgene of interest from a single transformation event into a dozen or more elite varieties (Meredith, 2006). As described previously, the final step in classical backcross breeding is several generations of selfing to “fix” the gene in each variety. *C. dentata* is an obligate outcrossing species (Rutter *et al.*, 1990), making it impossible to use self-pollination to produce varieties that breed true for blight resistance. However, such uniformity may be both undesirable and unnecessary. Foresters practicing traditional long-rotation forestry (defined here as at least 25 years from planting to harvest) are accustomed to dealing with highly genetically variable populations of trees.

One approach to producing a genetically diverse seedling population with a high proportion of blight resistant trees is a seed orchard of

somewhat novel design. The New York State Chapter of the American Chestnut Foundation has approximately a dozen germplasm archives containing open-pollinated progeny from more than 50 *C. dentata* parent trees. Most were planted at wide spacing and are suffering considerable mortality from chestnut blight and deer damage (Macfee, 2001). These gaps will allow room for interplanting with transgenic trees. Because the small transgenic trees would be planted among established wild-type trees, bulk collection of open-pollinated seed from the whole orchard would contain only a small proportion that carry the transgenes of interest. However, approximately 50% of the nuts collected from the transgenic trees would inherit the resistance gene and the linked *bar* gene. The selectable marker gene *bar*, in combination with the herbicide Finale, has proven to be effective in selecting for transformation events *in vitro* (Polin *et al.*, 2006; Rothrock *et al.*, 2007). The *bar*–Finale combination may also prove useful in identifying seedlings containing the transgenes by mass screening in nursery beds for herbicide tolerance. Such a screened seedling population would undoubtedly contain escapes, but this would be in exchange for the enhanced genetic diversity provided by the wild-type pollen parents and would probably be acceptable for reforestation.

Traditional long-rotation silviculture usually includes several intermediate cuts before plantations reach final harvest age. Considerable natural mortality is also expected (Nyland, 2002). Given these two assumptions, 50% or even 75% blight susceptible escapes should be acceptable in commercial planting stock. Susceptible wild-type trees would be removed by natural mortality and intermediate cuts, and the final harvest would be essentially the same as if the entire stand had been planted with blight resistant seedlings.

3.4 Conserving the Genetic Diversity of Remnant American Chestnut Populations

In the emotionally charged climate that surrounds the deployment of transgenic plants, the authors were hesitant to discuss introgression of transgenes into remnant populations, however, the ultimate goal of the American Chestnut Foundation is to

restore the species throughout its former range. Once the APHIS-BRS and the Environmental Protection Agency (EPA) regulatory requirements for “full deregulated status” have been met, the transgenes have been clearly shown to provide resistance to chestnut blight, and the transgene products have been proven to be safe for human and animal consumption, it is the intent of the NY Chapter of the American Chestnut Foundation to encourage its members to plant blight-resistant seedlings near flowering wild-type trees to *encourage* introgression into these remnant populations. Such purposeful introduction of transgenes for blight resistance into natural populations may meet with some opposition. We argue, however, that such introgression is a highly desirable outcome. The long-term survival of the American chestnut will be enhanced if resistance genes are allowed to introgress into and revitalize these remnant populations. This will help recreate a vigorous and self-sustaining species. Powell *et al.* (2005) and Merkle *et al.* (2007) made a strong case that the reintroduction of blight resistant chestnut trees will counteract the century-long disruption to the environment caused by the original introduction of chestnut blight.

3.5 Cutting-Edge Technologies

3.5.1 Cotransformation

Green fluorescent protein has proven to be a highly effective scorable marker in American chestnut (Polin *et al.*, 2006) and in many other species (see for review, Stewart, 2006). This marker allows nondestructive detection of transformed cells and their development into transgenic somatic embryos. It is not uncommon when using selectable marker genes such as BAR with PPT selection, that a significant number of escapes (nontransgenic cells or embryos that survive the selection) are obtained (Lebedev *et al.*, 2002; Reustle *et al.*, 2003; Dolgov and Skryabin, 2004). Using GFP screening in combination with BAR selection greatly reduces escapes (Tain *et al.*, 1997).

Although *gfp* is considered one of the environmentally safest marker genes (Jaiwal *et al.*, 2002), there still is public resistance to its use because of the confusion between “glowing” and “fluorescence”. “Glowing” brings to mind

something unnatural, while “fluorescence” is natural and is often seen in everyday objects. Until there is general public acceptance for GFP, the best strategy is to take advantage of GFP while keeping the option open for removing it later through breeding. One way to accomplish this is to perform a co-transformation (Brasileiro and Aragao, 2001) in which the GFP marker gene is on a separate vector construct from the resistance-enhancing gene. In this method, two or more *Agrobacterium* cultures, each containing a different vector construct, are mixed and used to co-inoculate the plant tissue. As many as four vector constructs have been used to co-transform aspen, resulting in 35%, 27%, 19%, and 19% of transgenic events containing one, two, three, or four constructs, respectively (Li *et al.*, 2003). In preliminary experiments with American chestnut somatic embryos, using selection for only one of the two vectors, approximately 40% of the transformation events contained the nonselected vector. The advantage of using co-transformation is that the transgenes will often be incorporated in different chromosomes of the plant. Therefore, the *GFP* marker gene can be used to identify the first generation of transgenic plants, but if needed, the *GFP* gene could be removed by breeding and selection for offspring that retain the resistance-enhancing gene but not the *GFP* marker. The method can be used for any combination of transgenes that need to be segregated at a later date.

3.5.2 The OxO gene and VspB promoter

The first transgenic American chestnuts to reach field tests contain an oxalate oxidase transgene that comes from wheat and is expressed by a vascular promoter that comes from soybean. Oxalate oxidase catalyzes the degradation of oxalic acid (also called oxalate) into H_2O_2 and CO_2 . The OxO enzyme is of interest because *C. parasitica*, the chestnut blight fungus, produces large amounts of oxalate at the canker margin, which helps lower the pH to toxic levels and binds calcium (Roane *et al.*, 1986). Oxalic acid has also been associated with pathogenesis in other fungi (Noyes and Hancock, 1981; Marciano *et al.*, 1983; Cessna *et al.*, 2000).

The *OxO* gene has been shown to enhance pathogen resistance in several transgenic crop species including soybean, peanut, and sunflower (Donaldson *et al.*, 2001; Liang *et al.*, 2001; Burke and Rieseberg, 2003; Cober *et al.*, 2003; Heritage, 2003; Livingstone *et al.*, 2005). Liang *et al.* (2001) demonstrated that constitutive expression of *OxO* in hybrid poplar enhanced resistance to the fungal pathogen *Septoria musiva*, another oxalic-acid-producing pathogen. Welch *et al.* (2007) showed that the *OxO* transgene protects lignin formation in transgenic chestnut callus tissues exposed to oxalic acid. Lignin biosynthesis is a critical step in forming a barrier zone around developing canker margins, which, in turn, is an important feature in chestnut blight resistance (Hebard *et al.*, 1984). The *OxO* gene was also selected because it comes from wheat, a familiar crop species that is consumed by most people every day. It, therefore, brings with it a sense of familiarity.

Driving the expression of the *OxO* transgene is a regulated promoter that can control which plant tissues express the gene. In the pTACF3 vector construct, the promoter from the *VSPB* gene was chosen because its expression pattern is primarily in stems and wound sites, the tissues that are the primary infection sites of the chestnut blight, but it is not expected to be produced in significant amounts in the nuts. Vascular expression of this transgene is intended to minimize effects on nontarget organisms without sacrificing effectiveness against *C. parasitica*.

3.5.3 Establishment of somatic embryo cell lines from leaf tissue

Most somatic cell lines are established using immature zygotic embryos as explants. Corredoira *et al.* (2003, 2006) were able to establish somatic cell lines from recently unfurled leaves from micro-propagated shoot cultures of European chestnut. These shoot cultures had been established from parent trees two years of age. If this technique can be extended to mature trees of any age, it will be possible to transform blight resistance genes or other genes of interest into clonally propagated commercially accepted varieties. An alternative procedure for obtaining somatic embryogenesis from material collected from trees was reported in the related species *Quercus robur* (Toribio *et al.*,

2004; Valladares *et al.*, 2006). In this case, somatic embryos were induced in expanding leaves of epicormic shoots forced from branch segments taken from mature (over 100 years old), selected trees. Attempts will be made to obtain a similar somatic embryogenesis system for mature chestnut trees.

ACKNOWLEDGMENTS

The European chestnut research was partially supported by MEC and Xunta de Galicia (Spain) through the projects AGL2005-00709/FOR, AGL2006-01387/FOR, and PGIDIT03 BTF40001PR, respectively. The American chestnut research was partially supported by ArborGen LLC (Summerville, South Carolina, USA); the New York State Chapter of the American Chestnut Foundation (Buffalo, New York, USA); the Monsanto Fund (St. Louis, Missouri, USA), the USDA-CSRS, McIntire-Stennis Research Program; the Consortium for Plant Biotechnology Research (St. Simons Island, Georgia, USA); and a special appropriation from the New York State Legislature (Albany, New York, USA).

1. INTRODUCTION

1.1 History, Origin, and Distribution

The birch family (Betulaceae) consists of 6 genera (*Betula*, *Alnus*, *Carpinus*, *Corylus*, *Ostrya*, and *Ostryopsis*) and about 150 species (Furrow, 1990). On the basis of extensive leaf and pollen fossil records, the Betulaceae is believed to have originated during the late Cretaceous period. The pollen records show that *Betula* and *Alnus* were differentiated already in the Santonian (80 Mya (million years ago); Crane and Stockey, 1987). Although earlier fossil records of *Betula* from the Paleocene and early Eocene exist, the oldest and most complete specimens of *Betula* fossils are from the middle Eocene (45 Mya) and comprise several leaf remains as well as infructescences, staminate inflorescences, and fruits (Crane and Stockey, 1987; Crane, 1989). The fossils are assigned to the extinct species *Betula leopoldae*. Although the fossils of *B. leopoldae* are not precisely similar to any living species, they resemble the species of the subgenus *Betulenta*, such as *Betula alleghaniensis* (Crane, 1989).

In Europe, pollen of the genus *Betula* is well known from late Tertiary (Dickson, 1984). Also the recolonization of Europe by forest tree species after the last glaciation is well documented in the pollen fossil records (Huntley and Birks, 1983). Pollen data, as well as macrofossils, indicate that

birch was present in central Europe during the full glacial (Huntley and Birks, 1983; Willis *et al.*, 2000). Birch populations were not limited only to a few southern refugia, but were locally present in a belt that ran eastward into Russia, and also on the northern European plains. Furthermore, birch pollen was widely present in parts of the central and northern Europe during the late-glacial period (Willis *et al.*, 2000). When the ice started to retreat, silver birch, as a pioneer species, occupied suitable habitats and quickly spread northward. Studies on chloroplast genome have proved that after the glaciation Europe was reoccupied by two main waves of recolonization: one from east and one from west (Palmé *et al.*, 2003). Following these two main waves of recolonization, today's silver birches in Europe can be classified into two main chloroplast haplogroups, of which one is dominant in the northwest and the other in the southeast and east. To Fennoscandia birch migrated about 10 000 years ago from refugia located to southwest, south, and southeast from Finland (Huntley and Birks, 1983; Hyvärinen, 1987; Willis *et al.*, 2000). The recolonization of North America by forest tree species after the last glaciation has recently been studied by Williams *et al.* (2001, 2004).

The modern birches are common trees and shrubs of boreal and north temperate zones of the northern hemisphere (Furrow, 1990) (Figure 1). The greatest species diversity occurs in the mixed mesophytic forests of eastern Asia, but the family

Figure 1 A Finnish birch forest

is ecologically important throughout middle and high latitudes where they range in habit from dwarf shrubs of arctic tundra to large trees of subtropical forests. The northern white birches (e.g., *Betula pendula* Roth, *Betula pubescens* Ehrh., and *Betula*

papyrifera Marsh) are relatively fast-growing and short-lived pioneer species requiring high light intensity, “colonizers par excellence” (Ashburner, 1993a), whereas the birches of more southern mixed mesophytic forests (e.g., *B. alleghaniensis*

Britt., *Betula grossa* Sieb. and Zucc., and *Betula maximowicziana* Reg.) are longer lived, less light-demanding, often dark-barked species that are not so easily shaded out, and maintain their place in canopy as occasional individuals (Schilling, 1989; Perala and Alm, 1990; Ashburner, 1993b).

1.2 Taxonomy, Genome Size, and Cytological Features

The genus comprises approximately 30–35 species (Furrow, 1990; de Jong, 1993), but the range of accepted species by different authors ranges from 30 to over 150 (de Jong, 1993), and considerable controversy still exists regarding the systematics of the genus. The uncertainty of the number of species and their phylogenetic relationships are mostly due to the high polymorphism in morphology. Furthermore, hybridization is very frequent, and for this reason, introgression, the transfer of genes between species, may have played an important part in the evolution of the genus (Alam and Grant, 1972; Furrow, 1990; Atkinson, 1992).

Taxonomically, the birches are a difficult group, not only because of their high vegetative variability and frequent hybridization, but also partly because of the confusions related to the binomial nomenclature. Many birch species have at least two different commonly used Latin names (i.e., *B. pendula*/*Betula verrucosa*/*Betula alba*, *B. pubescens*/*B. alba*) and these names are used in parallel with each other. Furthermore, variation in common names is even greater. For example, *B. pendula* is called as a silver birch, weeping birch, and European white birch.

Different attempts to identify sections or subgenera, and the relationships among the *Betula* species have been made on the basis of morphology, biochemical characters, and/or chromosomal numbers (Regel, 1865; Winkler, 1904; Nakai, 1915; Komarov, 1936; Pawlowska, 1983; de Jong, 1993; Keinänen *et al.*, 1999a). Regel (1865), the original monographer of *Betula*, divided birches into two main sections, *Eubetula* and *Betulaster*. The *Eubetula* section was further divided into three subsections, *Albae* (white birches), *Costatae* (yellow birches), and *Nanae* (dwarf birches). The section *Betulaster* contained only few Asian birches in the subsection *Acuminatae*. Since then this division has been

revised numerous times by number of authors into different subsections or subgenera (summarized in Furrow, 1990; de Jong, 1993).

Phylogenetic relationships within the genus *Betula* (Betulaceae) have been studied using two flower-specific silver birch genes, *BpMADS2* and *BpFULL1* (Järvinen, 2004), the *ADH* (alcohol dehydrogenase) gene (Järvinen *et al.*, 2004), nuclear ribosomal DNA (nrDNA) ITS (internal transcribed spacer) sequences (Li *et al.*, 2005), and the chloroplast *matK* (maturase K) gene and parts of its upstream and downstream flanking regions (Järvinen *et al.*, 2004). In general, the results obtained from the nuclear *ADH*, *BpMADS2*, and *BpFULL1* genes fit rather well with the infrageneric classifications proposed for birches (e.g., Regel, 1865; Winkler, 1904; de Jong, 1993), except for *Betula schmidtii* and *Betula ermanii* (Järvinen, 2004; Järvinen *et al.*, 2004). In all phylogenetic trees *B. schmidtii* (subgenus *Neurobetula*) grouped with the species in the subgenus *Betula* (including *B. pendula* and all other white birches), and *B. ermanii* (subgenus *Neurobetula*) grouped with the species in subgenus *Chamaebetula* (including *Betula humilis* and *Betula fruticosa*). The chloroplast *matK* data, with only five parsimony informative characters, divided the *Betula* species into two groups: one containing the American species *B. papyrifera*, *B. lenta*, and *B. alleghaniensis*, and the other including all the other species studied (Järvinen *et al.*, 2004).

Living species of *Betula* are all $n = 14$ or higher, but there is no unanimity on the base number of the genus (see Furrow, 1990). The base chromosome number 14 is commonly accepted, but Brown and Al-Dawoody (1979) found that meiotic behavior in hybrid birches ($2n = 42$) suggests that these trees are actually hexaploids, not triploids, which leads to a base chromosome number of 7. Furthermore, in meiosis the chromosomes in the $2n = 28$ and $2n = 56$ plants tend to lie in groups of 7 and for this reason the original basic chromosome numbers of birches is thought to be 7 rather than 14 (Eriksson and Jonsson, 1986). The small number of quadrivalents during the meiosis (multivalent chromosomes, which develop from four chromosomes during the meiosis) has also been thought to support the base number of 7. The DNA density for *B. papyrifera* with 84 chromosomes was equivalent to plants that would

possess 63 somatic chromosomes (Grant, 1969). Since a DNA value equivalent to 63 chromosomes is a multiple of 7 and not for 14, this suggests that the genomic number of *Betula* is $n = 7$. Also, the latest studies with molecular markers offer evidence for a base number of 7 in *Betula* (Williams and Arnold, 2001). Stebbins (1971) estimated that approximately one-third of the angiosperm plants possess more than two complete genomes (i.e., multiplied sets of the diploid chromosome number of the genus), and it is probable that also the present basic chromosome number of the genus *Betula* is of ancient polyploid origin. Various researchers have also postulated that the original basic number for the woody angiosperms, including birches, as well as for the angiosperms as a whole is $n = 7$ (Raven and Kyhos, 1965; Ehrendorfer *et al.*, 1968; Raven, 1975).

Polyploidy is a prominent process in plants (e.g., Wendel, 2000; Adams and Wendel, 2005). Species of *Betula* form a polyploid series, with chromosome numbers of $2n = 28, 56, 70, 84$, and 112, and additional numbers in some hybrids (reviewed by Furlow, 1990). From the evolutionary point of view, the genus *Betula* is still young and probably still evolving (Jäger, 1980; de Jong, 1993), which partly explains the polyploid nature of the genus and the occurrence of various ploidy levels (Särkilähti and Valanne, 1990). Furthermore, the differences in ploidy levels among the different subsections/subgenera indicate that several independent polyploidizations have occurred within the genus.

The DNA amount in the unreplicated haploid nucleus of an organism is known as its C-value (Swift, 1950). C-value is irrespective of the ploidy level of the taxon and it equals to genome size in diploid species, but always exceeds genome size in polyploid species. Nuclear DNA C-values differ about 1000-fold among angiosperms, ranging from about 0.1 pg (picogram) to about 125 pg per cell, and tend to be characteristic for a taxon (Bennett *et al.*, 2000). No published estimate of the genome size of *B. pendula* exists, but for another diploid representative of white birches, *Betula populifolia*, the C-value is 0.20 pg per cell (Olszewska and Osiecka, 1984; <http://www.rbgekew.org.uk/cvalues>). The closely related tetraploid *B. pubescens* has a genome size of C DNA = 0.75 pg per cell (Mowforth, 1986; <http://www.rbgekew.org.uk/cvalues>). When

all else is equal, the DNA amounts for polyploids are expected to increase in direct proportion to ploidy level. This means that tetraploids (such as *B. pubescens*) are expected to show double the mean C-value for diploids (such as *B. pendula* and *B. populifolia* (Bennett *et al.*, 2000)). However, the reported C-value for tetraploid *B. pubescens* (0.75 pg per cell) is almost four times higher than that for diploid *B. populifolia* (0.20 pg per cell). One interpretive factor could be intron size differences (e.g., Wendel *et al.*, 2002) caused by insertions/deletions between diploids and tetraploids or higher species, such as seen in *ADH* gene in *B. pubescens* and *B. papyrifera* compared to diploid *B. pendula* and *B. populifolia* (Järvinen *et al.*, 2004). At present, however, there is only little information on the correlation between genome and intron sizes in plants (Wendel *et al.*, 2002).

1.3 Habit and Habitat

Economically, the most important species is the diploid ($2n = 28$) silver birch (*B. pendula* Roth), which belongs to the variable white birch complex (*B. alba* L. *sensu lato*), sometimes considered geographic races of a single species, or as an aggregation of more or less closely related different species, subspecies, and hybrids (Furlow, 1990). Silver birch and the polyploid downy, or hairy birch, (*B. pubescens*) are distributed throughout the northern Eurasia; but silver birch extends further south than downy birch, whereas downy birch is more northerly and easterly in distribution (Atkinson, 1992). The southern limit of silver birch appears to be limited by the average July rainfall of 10 mm, and the northern limit by protection from cold northeasterly winds (Atkinson, 1992). In general, silver birch is restricted to drier and lighter soils, whereas downy birch grows in wetter soils. Silver birch grows up to 30 m high, usually with one stem (Atkinson, 1992). The bark of silver birch is smooth and silvery white and exfoliates in long, thin strands. In young trees (up to 10 years old) the bark is light brown, while in old trees the basal part of the trunk is black and vertically fissured. Young branches are spreading or ascending, whereas older branches are often pendulous. Silver birch is a wind-pollinated, outcrossing species with monoecious and a diclinous flowers. The male flowers consist of a minute perianth and two

stamens, whereas the female flowers consist only of a pistil, having no perianth.

1.4 Traditional and Molecular Breeding: Promises and Constraints

Silver birch is one of the three most important forest tree species, and the most important deciduous tree species in Nordic countries, and used, for example, in plywood, pulp, and furniture production. Breeding of silver birch can be considered to have started in late 1940s by selection of so-called “plus trees” on the basis of the growth and stem characteristics of the tree. The objective of the selection of plus trees was to use them in crossing experiments and establish field trials in order to screen genotypes with superior, heritable growth characters. The superior genotypes were selected for seed orchards that were established in polythene tunnels for the production of genetically improved birch seed for forest cultivation. Nowadays almost all birch seed (90%) used in nurseries in Finland originates from the birch seed orchards (Haapanen and Mikola, 2004). From a biological point of view, silver birch has several advantages in comparison to the breeding of boreal conifers, Scots pine, and spruce (for a review, see Koski and Rousi, 2005). The large genetic variation of silver birch (e.g., Howland *et al.*, 1995; Keinänen *et al.*, 1999b; Laitinen *et al.*, 2000; Rusanen *et al.*, 2003; Pritinen *et al.*, 2003) offers a thankful starting point for selection and breeding. Flowering at an early age allows a faster breeding cycle, and occurrence of interspecific hybridization and natural polyploidy offer optional breeding methods besides conventional selection. Remarkable genetic gain has already been achieved by using conventional breeding; for example, the stem volume of silver birch has been increased about 30% (Hagqvist and Hahl, 1998).

Despite the fact that silver birch is the main deciduous species of conventional tree breeding in Finland (Haapanen and Mikola, 2004), it has still undergone relatively little breeding. This is mainly because conventional breeding of woody plants is very slow compared to annual plants due to long generation cycle, large size of the trees, and long time needed for testing of many economically important properties. Also the phenotypic variation of many commercially

important and desired traits of forest trees is complex, and regulated by many loci (Neale and Savolainen, 2004). To speed up breeding of silver birch, new biotechnological approaches have been introduced, including marker-assisted breeding, micropropagation, and gene transfer. Several research groups are now studying the possibilities to improve wood quality, ozone, and drought and freezing tolerance, and insect and pathogen resistance of trees by using these technologies. However, for the time being, molecular breeding and use of genetically modified (GM) plants in silviculture are strictly controlled in the European Union (EU), and the possible use of transgenic plants has inflicted strong public concern about the putative environmental risks associated with GM plantations. For a review of regulatory considerations for transgenic trees, see Nehra *et al.* (2005).

2. DEVELOPMENT OF TRANSGENIC BIRCHES

2.1 Micropropagation and Gene Transformation

Silver birch micropropagation has been reported by many researchers, e.g., by Chalupa (1981), Ryyänen and Ryyänen (1986), Särkilähti (1988), Törmälä (1990), and Jokinen *et al.* (1991), and reviewed by Meier-Dinkel (1992). Micropropagation is relatively straightforward and succeeds routinely also from mature trees, with few exceptions (K. Keinonen, personal observation). During establishment of the shoot culture, a low level of cytokinin ($0.4\text{--}0.6\text{ mg l}^{-1}$) and a very low level of auxin ($0.001\text{--}0.05\text{ mg l}^{-1}$) have been used. Micropropagation of related species, such as *Betula platyphylla* var. *szechuanica* (McCown and Amos, 1979), *Betula celtiberica* (Perez and Postigo, 1989), *B. papyrifera* (Minocha *et al.*, 1986), and *B. pubescens* (Kauppi *et al.*, 1999) has also been described.

Induction of adventitious shoot buds, which are needed for plant regeneration from, for example, transgenic cells, has been reported to occur in *B. pendula* via callus (Huhtinen and Yahyaoglu, 1974; Simola, 1985; Srivastava *et al.*, 1985; Welander, 1988), through direct organogenesis from leaf discs (Piagnani *et al.*, 1990; Leege and

Tripepi, 1993), and from stem segments (Chalupa, 1981). Somatic embryogenesis has been used in large-scale propagation with several woody plants (Jain *et al.*, 1996), and embryogenic cultures have been used in transformation both with biolistic and *Agrobacterium*-mediated methods. With silver birch, somatic embryogenesis has been described by Kurtén *et al.* (1990), but its usage in transformation of birch has not been reported.

Micropropagated and seed-born silver birches have been compared in field tests. Viherä-Aarnio and Velling (2001) found no differences between them in survival, in height growth, or in biotic damage. Instead, differences among birch clones were very large, indicating that careful selection and field testing are needed before wide-scale practical forest cultivation using micropropagated plants can take place. In a 7-year field experiment, Jones *et al.* (1996) compared the growth of trees produced from nodal stem sections or callus tissue with that of seedlings. Micropropagated trees were found to grow at a similar rate compared to trees originating from seeds.

Transgenic birches have been successfully produced both with biolistic and *Agrobacterium*-mediated gene transfer (see Tables 1 and 2). With biolistic method, the gene transfer frequency was reported to be 6% (Valjakka *et al.*, 2000). Similar or lower numbers in frequency have usually been achieved with *Agrobacterium*-mediated transformation with most of the birch clones. One reason for the low success is the pathogenicity of *Agrobacterium*. Infection of birch tissue leads usually to severe hypersensitive response (HR). The tissue becomes necrotic or transparent in a few days after the beginning of co-culture. The strength of HR can be limited in several well-known ways: (1) by reducing compounds such as thiosulfate and cysteine, (2) with antioxidants,

(3) with polyvinylpyrrolidone or charcole, which adsorb phenolic compounds, (4) with inhibition of ethylene synthesis or action, and (5) by incubation of cultures under low light and at lowered temperature. The use of a liquid co-culture medium instead of a solid medium has proved to be especially effective in limiting the HR (Keinonen, 1999).

In flowering-related studies in the University of Joensuu, Finland, early-flowering birch clones have been used (Lemmettyinen *et al.*, 1998). Optimization of transformation protocol for these clones increased the transformation frequency up to about 90%. With 25 gene constructs, over 1000 transgenic lines have been produced during the recent years. In flowering-related transformations, it is necessary to produce about 20 transgenic lines with every construct in order to create at least a few strong transgenic phenotypes. With some exceptions, plants of only about one-third or one-fourth of the transgenic lines have proved to have proper phenotypes for further studies.

For the long-term storage of valuable germplasm, whether transgenic or in conventional breeding, a reliable method of cryopreservation for silver birch is now available. After cryopreservation, regeneration percentage is about 40% for the *in vitro* material (Ryynänen, 1998), and over 70% for the *in vivo* material (Ryynänen *et al.*, 2002). Furthermore, the stability and the function of the transferred genes of the regenerated plants were found to be maintained (Ryynänen *et al.*, 2002).

2.2 Flowering

In contrast to the great variation in their vegetative parts, birches are rather uniform in their reproductive organs, including separate male and

Figure 2 Silver birch: (a) male and female inflorescences and (b) germinating pollen grains in stigmas of female flower

female catkins. The male inflorescences develop at the ends of long shoots, and the female inflorescences at the ends of short side shoots (MacDonald and Mothersill, 1987; Atkinson, 1992). The flowers are in groups of three in the axils of three fused scales. The female flowers consist of a bicarpellate ovary with one anatropous ovule in each locule (Furlow, 1990; de Jong, 1993). The male flowers consist of a reduced perianth with one to four reduced tepals and one to four bifid stamens. The female inflorescences are produced in axillary buds and start to develop in mid summer. They overwinter inside buds, emerge usually in early May, and pollination takes place thereafter (Figures 2a, b). The male inflorescences develop inside the terminal buds and emerge in mid summer, overwintering about 30–40 mm long. The anthesis usually takes place in early May.

In general, trees are characterized by a long-lasting juvenile stage. In birch, it takes around 5–10 years until they start to flower in the field. In greenhouse conditions, this time can be reduced to 3 years (Viherä-Aarnio and Rynänen, 1994). The long juvenile period makes the breeding of birches slow and, therefore, accelerated induction

of flowering would be beneficial for breeding purposes. On the other hand, the prevention of flowering is necessary for the cultivation of transgenic trees.

The long juvenile period also makes the research of birch flower development tedious. In addition, the production of transgenic birch lines itself takes about 1 year (Keinonen, 1999). Fortunately, there is a lot of variation in flowering times of birches. By means of conventional breeding, the juvenile, nonflowering period has been reduced to few months (Stern, 1961). The clones originated from these early-flowering birches have proved to be very useful in flowering research (e.g., Lemmetyinen *et al.*, 1998; Lemmetyinen and Sopanen, 2004).

2.2.1 Genes controlling flower development in birch

The genetic regulation of birch flowering has been studied especially in University of Joensuu, Finland, where Tuomas Sopanen's group has been developing methods to prevent the spread of

transgenes in birch by making them nonflowering. The group has isolated several genes involved in the regulation flower development in birch. The group has concentrated mainly on MADS-box genes, which form a large group of transcription factor genes regulating different processes in plant development. In *Arabidopsis*, about 107 different MADS-box genes have been identified (Parenicová *et al.*, 2003), and a large number of the characterized MADS genes are related to flowering. In silver birch, the Sönanen group has characterized eight different MADS-box genes (Lemmettyinen and Sönanen, 2004).

BpMADS1 is a birch ortholog for *SEPALLATA3* (*SEP3*) (Lemmettyinen *et al.*, 2004a). In *Arabidopsis*, *SEPALLATA* genes (*SEP1–4*) are necessary for flower development. Without the activity of these *SEPALLATA* genes the flower organs (sepals, petals, stamens, and carpels) are converted into leaflike organs (Ditta *et al.*, 2004). *BpMADS1* is expressed in the inflorescence meristem for a relatively short period. The expression reappears later in developing flowers, especially in stamens and carpels. The ectopic expression of *BpMADS1* under the control of cauliflower mosaic virus (CaMV) 35S promoter accelerated flowering in tobacco and resulted in changes in the number and identity of floral organs in *Arabidopsis*. The suppression of the expression of *BpMADS1* in birch resulted, in some cases, in the transformation of male inflorescence growth into vegetative growth. As an inflorescence-specific gene, the promoter of *BpMADS1* has been used in the prevention of flowering (see below).

BpMADS2 and *BpMADS8* are birch homologs for *Arabidopsis* B-function genes *PISTILLATA* (*PI*) and *APETALA3* (*AP3*), respectively (Järvinen *et al.*, 2003; Länneppää *et al.*, 2005a). The B-function is necessary for the development of petals and stamens (Jack *et al.*, 1992; Goto and Meyerowitz, 1994). *BpMADS2* has been used in studying the nucleotide variation of birch populations as well as the phylogeny of the genus *Betula* (Järvinen *et al.*, 2003; Järvinen, 2004).

Three of the birch genes isolated, *BpMADS3*, *BpMADS4*, and *BpFULL1* (FUL-like 1, formerly *BpMADS5*), belong to the *API/SQUA* group of plant MADS-box genes (Elo *et al.*, 2001). *BpMADS3* is most similar in sequence to *APETALA1* (*API*) and *SQUAMOSA* (*SQUA*)

while *BpMADS4* and *BpFULL1* are more closely related to *FRUITFULL* (*FUL*). *API* is an A-function gene necessary for the development of sepals and petals in *Arabidopsis*. All these three birch genes are expressed in both male and female inflorescences during the development, but *BpMADS4* is also expressed in leaves and roots. Overexpression of any of these genes in tobacco under the control of CaMV 35S promoter resulted in very early flowering. This suggests that these genes are likely to be involved in the determination of the identity of the inflorescence or floral meristem. They can also be used in biotechnological applications for acceleration of flowering.

Although the ectopic expression of *BpMADS3*, *BpMADS4*, or *BpFULL1* resulted in very early flowering in tobacco, there was a considerable difference between the flowering time of *BpMADS4* and *BpMADS3* sense plants in birch. While there seemed to be a critical size or age required for flowering in *BpMADS3* sense lines, the *BpMADS4* sense lines could make inflorescences extremely early (Elo *et al.*, 2007; Lemmettyinen *et al.*, unpublished results). Silencing of the *BpMADS4* expression using the antisense or RNA interference (RNAi) techniques delayed inflorescence development in transgenic lines (Elo *et al.*, 2007; Lemmettyinen *et al.*, unpublished results). Taking together, these results suggest that *BpMADS4* is involved in the regulation of the juvenility in birch. This finding is of special interest because the regulation of juvenility in trees is very poorly understood.

BpMADS6 is a birch ortholog for *Arabidopsis* *AGAMOUS* (*AG*) and is expressed in birch stamens and carpels (Lemmettyinen *et al.*, 2004a). The ectopic expression of *BpMADS6* resulted in early flowering in tobacco and *Arabidopsis* and also had some effects on the flower structure. Suppression of the expression of *BpMADS6* in birch resulted in the formation of male inflorescences without stamens or caused other abnormalities in the inflorescences. The putative birch homolog to *AGL11*, *BpMADS7*, is expressed in male and female inflorescences (Järvinen, unpublished results).

Two other non-MADS-box flowering-related genes have also been isolated: a birch homolog of *Arabidopsis* *LEAFY*, *BpFLO* (Hurmerinta and

Elo, unpublished results), and a birch SBP-box gene, *BpSPL1* (Lännempää *et al.*, 2004).

2.2.2 Generation of nonflowering birch

The main limitation for the cultivation of transgenic trees in the field is the risk of spreading of various transgenes into natural populations (Bhalerao *et al.*, 2003). The ecological consequences of the potential crossing of transgenic trees with native ones are hard to predict. Furthermore, governmental regulatory guidelines restrict the use of GM plants in EU and elsewhere. Thus, the long-term testing and cultivation of transgenic trees in the field is impossible unless the risk of spreading of the transgenes is eliminated. The most adequate way to ensure this is to prevent the spreading of transgenes via pollen and seeds by blocking the flower development completely. The use of nonflowering trees as recipients of economically important transgenes would be one effective way to prevent the spreading of transgenes into natural tree populations.

The amount of inflorescences produced per tree varies, but in general, adult birches produce great amounts of inflorescences. Silver birch is wind pollinated and the gene flow through pollen is very efficient (Atkinson, 1992). Furthermore, birch produces considerable amount of seeds (up to 100 kg ha⁻¹, or 150 000 seeds/m²) every year and the dispersal of seeds is also by wind. It is unclear, how much the allocation of resources to inflorescences reduces the vegetative growth. However, one could expect that the prevention of flowering would increase the growth, even substantially. Therefore, the inability to flower would itself be greatly beneficial. In addition, the birch pollen is highly allergenic, and an estimated 100 million individuals suffer from birch pollen allergy (Vrtala *et al.*, 2001). Depending on the amount of nonflowering birches planted, the quantity of allergenic pollen in the air could be, at least, locally reduced.

The flowering can be prevented by several different techniques, for example, by silencing the necessary gene(s) for flowering by using antisense or RNAi techniques, or by using tissue-specific ablation by using flower-specific promoter-cytotoxin gene construct (Figure 3). The regulation of flowering is however, highly complicated.

Figure 3 Strategy for the prevention of flowering using the tissue-specific ablation method

Single developmental processes are regulated by several genes that may also compensate each other's functions. Therefore, several genes must probably be silenced to prevent flowering, and the identification of a single gene, absolutely necessary for flowering, is difficult, or even impossible. However, in birch, *BpMADS4* is one of the central genes regulating flowering and can be used either to accelerate or prevent flowering (Elo *et al.*, 2007). The most reliable method to prevent flowering, however, has been the tissue-specific ablation.

The birch flowering was prevented, for the first time, by utilizing the promoter of *SEP3* ortholog *BpMADS1* (Lemmetyinen *et al.*, 2001, 2004a, b). The expression of *BpMADS1* is restricted to inflorescences, and therefore, its promoter is

suitable to regulate the expression of cytotoxic gene, *barnase*. The barnase is a ribonuclease isolated from *Bacillus amyloliquefaciens* (Hartley, 1989). The original barnase protein contains a signal peptide targeting the protein out of the cell. By deleting this sequence the gene efficiently kills the cell it is expressed in. The construct was first tested in tobacco and *Arabidopsis*, resulting in plants with nonflowering phenotype (Lemmetyinen *et al.*, 2001). Importantly, this study showed that the prevention of flowering is able to enhance vegetative growth. This can be explained at least partly by the change in growth habit. In wild-type tobacco, there was a cessation in vegetative growth during the development of terminal inflorescence and seed ripening. In nonflowering tobacco plants, the growth continued without cessation, or the cessation period was short during the time the plant tried to form inflorescence. In *Arabidopsis*, the construct prevented flower formation, and usually stalk formation as well. At times, some

shoots grew from many-leaf rosettes and formed rosettelike structure on the top, which was in turn, a base for the new shoot forming.

The development of birch inflorescences was also successfully prevented using the same *BpMADS1::BARNASE* construct (Figure 4a) (Lemmetyinen *et al.*, 2004b). However, in many transgenic lines the prevention of inflorescence formation was not complete, and many lines showed some disturbance in growth (Figure 4b). Although analyses of GUS (β -glucuronidase) construct lines showed that the isolated promoter fragment of *BpMADS1* lead to intense flower-specific expression in tobacco and *Arabidopsis*, it is possible that some important regulatory elements are missing. It is known that some regulatory elements of the promoters of MADS-box genes are located in introns (Sieburth and Meyerowitz, 1997; Hong *et al.*, 2003).

According to its sequence homology to *Arabidopsis FUL*, birch *BpFULL1* was predicted to be expressed early in the inflorescence development

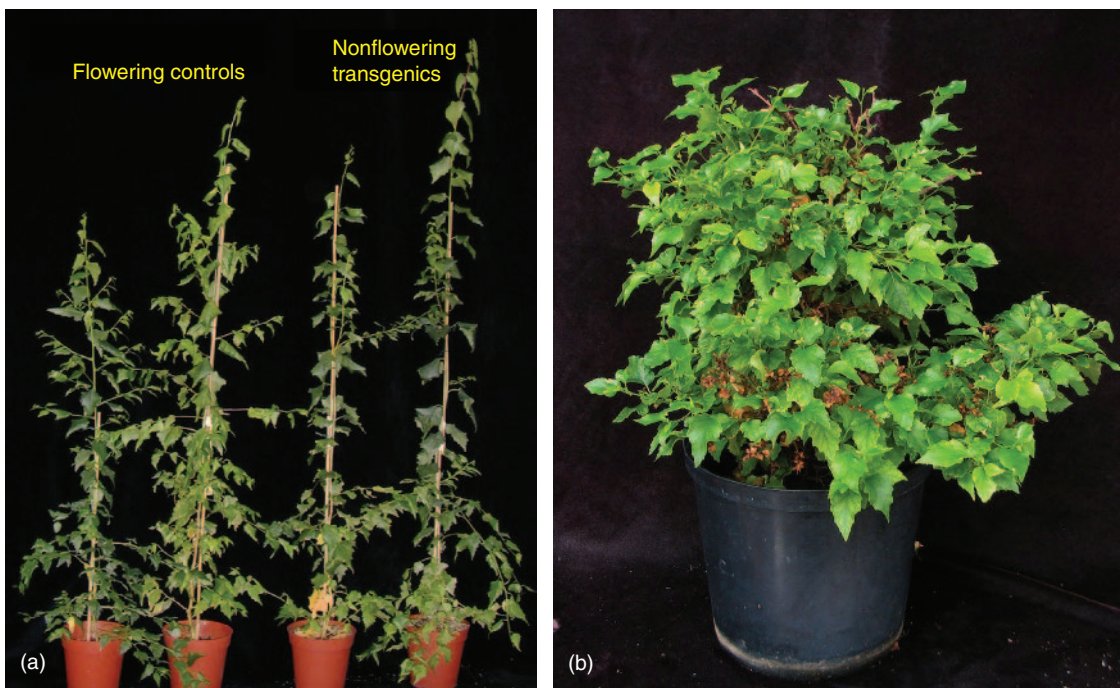

Figure 4 The nonflowering birches generated by introducing the *BpMADS1::BARNASE* gene construct into the early-flowering birch clone: (a) the two birches on the left are wild-type control plants forming inflorescences, the two birches on the right are transgenic plants, which do not form any inflorescences; (b) in some clones, the barnase construct has resulted in growth disturbances and “bonsai”-like phenotype

and function as a genetic switch between the shoot and floral development. The promoter-GUS analyses and *in situ* hybridizations further supported this hypothesis (Länneppää *et al.*, 2005b). The barnase construct with the 2.5-kb-long fragment of *BpFULL1* promoter prevented the development of inflorescences in transgenic *Arabidopsis*, resulting in a dramatic increase in the number of rosette leaves. In transgenic tobacco, the construct efficiently prevented the formation of inflorescences. Nonflowering birch lines with vegetative growth comparable to that of the wild-type birches were also generated. Artificial overwintering treatment demonstrated that the development of both male and female inflorescences was blocked. These results indicate that the *BpFULL1::BARNASE* construct is a very promising gene construct in preventing the flower development in various plant species and is likely to be the best construct available at the moment. The stability of the nonflowering phenotype in birch obtained using the *BpFULL1::BARNASE* construct is currently being tested in a long-time field cultivation experiment (see below).

The promoters of birch B-function genes, *BpMADS2* and *BpMADS8*, have been tested in the prevention of flowering (Länneppää *et al.*, 2005a). The birch gene *BpMADS2*, homologous to *Arabidopsis PI*, had been isolated previously (Järvinen *et al.*, 2003). *In situ* hybridization revealed that *BpMADS2* was expressed in male inflorescence meristems, stamen primordia, and later in stamens as well as in the carpel primordia (Länneppää *et al.*, 2005a). According to promoter-GUS analysis, the 3-kb fragment of *BpMADS2* promoter showed to be inflorescence-specific in *Arabidopsis* (Länneppää *et al.*, 2005a). The *BpMADS2::BARNASE*, in turn, resulted in malformed stamens and petals. Furthermore, flower development was totally prevented in several lines: the inflorescence stems grew and elongated continuously and produced cauline leaves. In tobacco, *BpMADS2::BARNASE* resulted in inflorescence stems lacking flowers. In birch, *BpMADS2::BARNASE* resulted in degenerated stamens after the overwintering treatment as well as malformed female inflorescences and reduced number of carpels in some of the lines.

BpMADS8 was shown to be homologous to *Antirrhinum DEFICIENS* (*DEF*) and *Arabidopsis AP3* (Länneppää *et al.*, 2005a). *BpMADS8*

was expressed in the birch male inflorescence meristems and the expression became stronger in the developing stamens. No expression was detected in tepals and bracts or in the female inflorescences. The promoter-GUS construct driven by a 2.4-kb-long promoter fragment of *BpMADS8* was shown to have specific expression in *Arabidopsis* stamens (Länneppää *et al.*, 2005a). The *BpMADS8::BARNASE* construct resulted in male sterility in *Arabidopsis*, but the carpels developed normally. In tobacco, empty buds or malformed floral organlike structures were produced. Most of the transgenic birches carrying *BpMADS8::BARNASE* construct grew normally, and produced normal female inflorescences after an artificial overwintering treatment. However, the male inflorescences were shorter and the stamens were malformed. No pollen was released from the inflorescences, or seen on the surface of the malformed anthers.

In most of the transgenic birch lines obtained, *BpMADS2::BARNASE* and *BpMADS8::BARNASE* constructs did not result in vegetative disorders. It has been reported that several research groups have attempted to produce sterile plants using B- and C-function gene promoters fused to cytotoxin genes (Van Der Linden *et al.*, 2002). However, these promoters have not been silent in vegetative tissues leading to severe development and growth impairment. Therefore, the *BpMADS2* and *BpMADS8* promoters seem to be very promising from the point of view of biotechnological applications. The corresponding *BARNASE* constructs could be used to induce male sterility or total prevention of flower development. The highly stamen-specific promoter elements of *BpMADS8* should be studied in more detail. When fully characterized, these elements could be used to engineer artificial promoters, which could be used to target transgene expression in the late stamen development.

2.2.3 Acceleration of flowering

The shortening of the juvenile phase of birches is possible by means of conventional breeding (Stern, 1961), or by altering conditions of culturing (see e.g., Meilan, 1997). The problem of conventional breeding is that the desired properties do not necessarily accompany the short juvenile period.

For example, the early-flowering birches bred by Stern (1961) were hardly suitable starting material for the breeding program for improving of birches because of their undesirable, shrubby growth habit. However, for the flowering studies, the early-flowering clones are valuable model plants.

The alteration of environmental conditions to accelerate flowering is a valuable tool in acceleration of birch breeding. Even the cultivation in the ordinary greenhouse shortens the juvenile period up to about 2 years (Viherä-Aarnio and Ryynänen, 1995), depending on the clone. By growing birches in continuous light and elevated CO₂ concentration the juvenile period has been reduced to few months (Holopainen and Pirttilä, 1978). However, the amount of acceleration of flowering is highly dependent on the genotype, which restricts the selection of different good genotypes.

The use of genetic modification has enabled the acceleration of flowering, at least in principle, regardless of genetic background. In trees, the target genes for genetic modification of flowering have been studied in many species, for example, in poplars, citrus, birch, eucalyptus, spruces, and pines (for a review, see Lemmetyinen and Sopanen, 2004).

The first demonstration of the transgenic acceleration of flowering in trees was achieved by the overexpression of *Arabidopsis* gene, *LEAFY* (*LFY*), which caused flower formation in hybrid aspen only after a few months (Weigel and Nilsson, 1995). In this case, however, the plants did not form normal inflorescences (catkins), but formed single male flowers. These flowers were sterile because the anthers did not open. In other poplars, the overexpression of *PTLF*, the poplar homologue of *LFY*, resulted in only a limited effect on flowering time (Rottmann *et al.*, 2000). In birch, the effect of overexpression of birch homologue of *LFY*, *BpFLO*, was dependent on birch clone (Lemmetyinen *et al.*, unpublished results).

The overexpression of *API* in citrus showed that the expression of this gene is sufficient to lead to the formation of normal, fertile inflorescences (Peña *et al.*, 2001). In birch, there are three characterized genes belonging *API/FUL* group, *BpMADS3*, *BpMADS4*, and *BpFULL1* (Elo *et al.*, 2001). They all have been effective in acceleration of flowering, and the overexpression of any of them resulted in early flowering in tobacco. The most

effective birch gene in this group was *BpMADS4*. On the basis of sequence comparison, the most similar gene in *Arabidopsis* is, however, a root-specific gene, *AGL79*, the function of which is still unknown (Parenicová *et al.*, 2003). The overexpression of *BpMADS4* in tobacco resulted in very early flowering, and the structure of whole plant resembled inflorescence.

Similarly, the overexpression either of *BpMADS3* or *BpMADS4* resulted in early flowering in birch (Figure 5) (Elo *et al.*, 2007; Lemmetyinen *et al.*, unpublished results). While the plants overexpressing *BpMADS3* required a certain size before they started abundant flowering, the plants overexpressing *BpMADS4* started flowering even just after they had been transferred onto soil. Therefore, it seems that *BpMADS4* is involved in regulating the transition from juvenile phase to adult phase. The use of genes regulating the development of floral structures may, however, be problematic in the acceleration of flowering, because they may also cause some degree of sterility. This was also detected in the birches overexpressing *BpMADS3* or *BpMADS4* (Elo *et al.*, 2007; Lemmetyinen, unpublished results). Therefore, the use of the genes regulating flowering time exclusively might be more appropriate. Recently, promising results have been obtained

Figure 5 Early-flowering birch: early flowering was obtained by overexpressing *BpMADS4* in normally flowering birch clone (arrow indicates the male inflorescence)

from poplar by the overexpression of poplar homolog of flowering time gene *FLOWERING LOCUS T* (*FT*), *PtFT1*, which resulted in very early formation of inflorescences (Böhlenius *et al.*, 2006).

2.3 Resistance against Fungal Diseases

In general, birch is susceptible to detrimental pathogens only when the growth starts to decline at the age of 45–60 years. Silver birch is mainly rotted by *Polyporaceae* fungi, which start the rotting of timber in the heartwood and then proceed to the living sapwood (Uotila, 1987). Birch leaf rust, caused by the fungus *Melampsorium betulinum*, is the most important leaf disease both in plantations and in natural birch forests in Fennoscandia (Poteri and Rousi, 1996). Leaf rust causes yellowing and premature falling of the leaves, but it does not affect the wood. However, if leaf rust epidemics appear in several sequential years, the growth of young seedlings may decrease because of the shortened assimilation period (Uotila, 1987; Vuorinen, 1992). Some pathogenic fungi may cause stem lesions mainly in young birch trees, especially when the bark is damaged by forestry work or other agents or in fringe-area plantations. In young cultivated birch stands, firm rot around the pith is a serious cause of concern (Uotila, 1987). Several different pathogens (both fungi and bacteria) are responsible for this defect. Stem spotting disease caused by a group of fungi (e.g., *Fusarium avenaceum*, *Botrytis cinerea*, *Godronia multispora*, *Cylindrocarpon* spp., and *Alternaria* spp.) is common in nurseries and can be very harmful to young birch seedlings.

Advances in the research on the molecular mechanisms of disease resistance in crop plants has opened up possibilities for testing biotechnological applications for increasing disease resistance also in forest trees. These applications include introduction of genes encoding antimicrobial recombinant proteins of plant or nonplant origin into trees (e.g., Peña and Séquin, 2001). The possibilities to improve fungal disease resistance in silver birch have been tested by constructing and studying transgenic birch lines carrying a chitinase IV gene from sugar beet. Chitinases catalyze the hydrolysis of chitin, a β -1,4-linked polymer

of N-acetyl-D-glucosamine, which is the major component of the cell wall of most filamentous fungi (Bartnicki-Garcia, 1968). Hydrolysis of the chitin, found in the fungal hypha, by chitinases kills the fungus without causing damage to the plant cells. Sugar beet chitinase IV is a basic endochitinase belonging to class IV chitinases that are secreted extracellularly and deposited in the apoplast (Neuhaus *et al.*, 1991; Mikkelsen *et al.*, 1992). Sugar beet chitinase IV has been shown to inhibit the growth of the conifer pathogen *Heterobasidion annosum* *in vitro* (Susi *et al.*, 1995). In other studies, class I and V chitinases have been shown to inhibit the growth of various fungal species *in vitro* (e.g., Schlumbaum *et al.*, 1986; Mauch *et al.*, 1988; Arlorio *et al.*, 1992; Melchers *et al.*, 1994; Vierheilig *et al.*, 2001). Overexpression of chitinase genes has increased fungal disease resistance in many plant species (e.g., Broglie *et al.*, 1991; Grison *et al.*, 1996; Asao *et al.*, 1997; Lorito *et al.*, 1998), but so far the approaches employing transgenic chitinases in trees are in early stages of development.

Sugar beet chitinase IV gene with the enhanced (4 \times) CaMV 35S was transferred to silver birch through *Agrobacterium*-mediated gene transfer as described in Keinonen-Mettälä *et al.* (1998). The resistance of chitinase transgenic silver birch lines against fungal diseases was tested in a greenhouse and in a field trial. In the greenhouse experiment, the chitinase transgenic lines with high sugar beet chitinase IV expression showed improved resistance to the leaf spot fungus *Pyrenopeziza betulicola* (Fuckel) (Pappinen *et al.*, 2002). However, in a 3-year field trial, the chitinase transgenic birch lines did not differ from the control, or were more susceptible to the leaf spot fungus than the wild-type control trees (Pasonen *et al.*, 2004). The contradictory results from the greenhouse and the field trial may be due to the fact that only a high inoculum of one *P. betulicola* isolate was used to infect the plants in the greenhouse, while natural infection in the field consisted of various genotypes of the same pathogen. Also, several biotic and abiotic factors to which the plants were exposed in the field trial, but not in the greenhouse, have most likely influenced the fungal disease resistance of the studied birch lines. However, the results from the field trial revealed that some resistance against

the birch rust fungus *M. betulinum* was achieved (Pasonen *et al.*, 2004).

2.4 Insect Herbivory and Mammalian Herbivores

Silver birch is one of the most important food plants for insects in Finland (Annala, 1987). Of geometrid defoliators using silver birch as a resource, *Operophtera brumata* is among the most voracious species (Tikkanen *et al.*, 2000). The damage may be severe after the insect outbreak, but usually climatic conditions enable birch to compensate the damage by regrowth. Beetles may damage trunks of mature trees and thereby reduce the economical value of the timber (Raulo, 1981). For instance, *Hylecoetus dermestoides* and *Trypodendron signatum* bore tunnels in logs and timber. *H. dermestoides* can also attack living trees and a simultaneous infection by rot fungi can be fatal to the tree. Larvae of the birch cambium fly, *Phytobia betulae*, mines in the birch wood near the cambium layer and cause 1–4-mm-wide brown streaks in the wood (Annala, 1987). The streaks decrease the value of birch wood used in plywood and furniture industry, but the damage is purely aesthetic; the mechanical strength of the wood is not affected.

Birches are important winter food for many herbivorous animals, such as moose (*Alces alces*), hares (*Lepus*) and voles (*Microtus*, *Clethrionomys*) (Rousi *et al.*, 1989, 1990; Tahvanainen *et al.*, 1991). Voles cause considerable damage to forest plantations, especially during the peak years of density fluctuations, every third or fourth year. Voles destroy birch seedlings under snow cover and they can eat the bark of the seedlings until the basal diameter reaches 4 cm (when the seedling is about 5 years old). Hares feed on the upper branches of young birch seedlings and especially in a winter time the damage can be fatal for the seedlings. Moose browsing on young birch seedlings occurs throughout the year and can cause serious damage to birch plantations.

Although herbivory is clearly an important biotic stress factor causing reduction of growth and economical value of timber, the only biotechnological application reported so far appears to be the transformation of spider insecticidal

peptide gene into *B. platyphylla* in China (Zhan *et al.*, 2003). Insect feeding tests with *Lymantria dispar* showed that the development of the larvae was significantly retarded, but no information of possible field trials has been reported.

2.5 Wood Quality

Lignin is an undesirable wood component in pulp and paper industry, and manipulations of the content and subunit composition of lignin are among the most intensively studied biotechnological applications in forest trees. The extensive use of birch roundwood for chemical pulp emphasizes the need for understanding the wood properties and characteristics of lignin biosynthesis in birch (Aronen *et al.*, 2003). Lignin precursor biosynthesis involves a complex array of *O*-methyltransferases controlling the production of differentially methylated monolignols, which give rise to hydroxyphenol (H), guaiacyl (G), and syringyl (S) subunits of lignin (Boudet, 2000). Lignin accumulation and subunit composition can be biotechnologically altered by regulation of relevant enzymes by antisense, sense, or sense co-suppression techniques (Li *et al.*, 2003). The current knowledge emphasizes the essential role of 4-coumarate:coenzyme A ligase (4CL) (Hu *et al.*, 1999; Harding *et al.*, 2002) and caffeoyl coenzyme A *O*-methyltransferase (CCoAOMT) (Zhong *et al.*, 2000) in lignin biosynthesis.

Aronen *et al.* (2003) have studied the role of caffeate/5-hydroxyferulate *O*-methyltransferase (COMT) in lignin biosynthesis in birch. The constructs pRT99/35S-PtCOMT and pRT99/UbB1-PtCOMT carrying a bispecific caffeate/5-hydroxyferulate *O*-methyltransferase gene from *Populus tremuloides* were transferred into birch by using a biolistic microprojectile bombardment (Valjakka *et al.*, 2000). The aim of the transformation was to increase COMT activity and thus the amount of more easily degradable S units of lignin. COMT has also been reported to have 5-hydroxy-coniferaldehyde *O*-methyltransferase activity catalyzing the diversion of guaiacyl monolignol intermediates into syringyl types (Li *et al.*, 2000). Two transgenic 35S CaMV-PtCOMT and UbB1 (ubiquitin promoter from sunflower)-PtCOMT lines were

regenerated. The Klason determination of the 2-year-old stem material revealed no considerable alterations in the lignin content in three transgenic lines when compared to the control plants but in two lines the S/G ratio was reduced by 69–72%. Alterations in the S/G ratio were not detected in either of the UbB1-PtCOMT lines, but in one line the Klason lignin content was decreased. Aronen *et al.* (2003) concluded that the introduction of the sense construct of the *PtCOMT* gene into birch did not lead to the expected alterations in lignin composition but the results provide an insight into possibilities how lignin biosynthesis in birch can be modified by affecting the functioning of individual genes.

Seppänen *et al.* (2006) isolated a birch *4CL1* gene fragment and used it for antisense transformation of silver birch. The objective was to study whether the lignin content could be lowered and the subunit composition could be modified by *4CL* antisense transformation. Birch *Bp4CL1* complementary DNA (cDNA) was cloned in antisense orientation downstream of a 35S CaMV promoter in the pBI121 binary vector containing the *nptII* (neomycin phosphotransferase II) gene for kanamycin selection. *Agrobacterium* strain C58C1 (pGV2260)-mediated gene transfer (according to Keinonen-Mettälä *et al.*, 1998) with a binary vector system was used to introduce the *Bp4CL1* gene into birch. The transformation yielded three polymerase chain reaction (PCR) and Southern blot positive lines, which were studied in more detail. Lignin content was determined according to TAPPI-T 222 method, which separates the acid-insoluble fraction of lignin (Klason lignin) and the acid-soluble lignin. Quantitative analysis of the four most important structural units of lignin, β -O-4, β -5, β - β , and dibenzodioxocin was done using two-dimensional NMR spectroscopy as described in Heikkinen *et al.* (2003). Chemical composition of the stem wood of two of the lines did not differ from that of the control plants in the view of total lignin and cellulose contents, and monosaccharide and polysaccharide compositions. One line contained slightly more lignin and less cellulose compared to the other transgenic lines and the control. This line showed also significantly slower growth rate compared to the control plants. Seppänen *et al.* (2006) concluded that the antisense transformation of birch with *4CL* gene did not lead to expected

changes in wood chemistry but, instead, resulted in changes in growth characteristics, especially in root biomass and morphology.

2.6 Phytoremediation

Phytoremediation has received increasing attention in recent years and the possibilities to use genetic engineering in the improvement of plants for phytoremediation have been studied (for a review, see e.g., Kärenlampi *et al.*, 2000; Eapen and D'Souza, 2005). In addition to large size, forest trees have an extensive root system, which enables an efficient uptake of pollutants from the soil. The falling of leaves of deciduous trees in autumn makes the collection of the pollutant concentrated from soil easy.

Birch is quite tolerant to some toxic compounds found in contaminated soil and therefore, its ability to accumulate heavy metals and its suitability in phytoremediation have been studied by many groups (e.g., Eltrop *et al.*, 1991; Österås *et al.*, 2000; Rosselli *et al.*, 2003). Although birch is not considered as an accumulator but as a metal-tolerant plant, it transfers reasonably high concentrations of metals to its above-ground parts (Rosselli *et al.*, 2003). Differences have been found between birch clones in Cu and Zn tolerances (Denny and Wilkins, 1987; Utriainen *et al.*, 1997), and for this reason birch clones have been screened for their suitability to phytoremediation (Kopponen *et al.*, 2001). So far there are no reported transgenic applications on phytoremediation in birch but the results of poplars (Che *et al.*, 2003) indicate that trees form a potential group of plants.

2.7 Other Traits

The growth, in general, and especially the productivity are economically important. The maximum growth is a sum of several factors. Nitrogen metabolism is considered to be one of the critical factors restricting growth. In nitrogen assimilation, nitrate reductase (NR) (and nitrite reductase, NiR) is the central gene. Its regulation has been studied in birch (Friemann *et al.*, 1992; Hachtel and Strater, 2000), and amino acid sequence of its protein has been modified

(Schöndorf and Hachtel, 1995), but there are only a few attempts to improve nitrogen assimilation in birch by genetic modification. A field experiment with transgenic birch altered for carbon and nitrogen metabolism (sense-RbcS and NR lines) was established in year 2000 by Hely Häggman at the Punkaharju Research Station of the Finnish Forest Research Institute, Finland, but unfortunately the field experiment was destroyed in 2004.

Birches are also a source of chemical compounds. Whiteness of *Betula* bark is due to the development of the white wax betulin (Ashburner, 1993b). Betulin is a naturally occurring triterpene found predominantly from the bark of birch trees and it can form up to 30% of the dry weight of the bark (Alakurtti *et al.*, 2006). The high availability of betulin from the birch bark and easiness of its isolation make it a potentially important raw material for some polymers. On the other hand, betulin can be easily converted to betulinic acid, which has been shown to possess a wide spectrum of biological (antifungal) and pharmacological (antimalarial, antitumor, and anti-inflammatory) activities. Thus, modification of the respective biosynthetic routes shows potential for production of promising chemicals for pharmacological applications, but no plans to achieve this have so far been reported.

2.8 Testing: A Need for Field Trials

As sessile organisms, higher plants exhibit a great degree of plasticity in response to environmental stimuli. The regulation of gene expression is the key process for adaptation to changes in environmental conditions, and thus for survival. High genetic diversity means ability to adapt to changing environmental conditions. This is important especially for long-lived species, such as forest trees, that are subject to environmental conditions varying greatly from year to year. GM plants are first tested in greenhouse, but the testing is largely done in controlled environmental conditions. In natural environments, however, GM plants are exposed to conditions that are highly variable and fluctuations are often both irregular and stochastic. Hence, long-term field trials in testing GM trees are highly important. The importance of field trials is also emphasized by the varying results from the greenhouse and

field trial studies as was reported by Pappinen *et al.* (2002) and Pasonen *et al.* (2004).

A 3-year field trial of transgenic silver birch was conducted in Helsinki (Finland) in 2000–2003 in order to produce information that could be utilized in assessing the risks of GM birch. The information collected from the field trial focused on the biological interactions between chitinase-transgenic birch and other organisms, i.e., pathogenic and mycorrhizal fungi, and herbivores. The expression of the sugar beet chitinase IV gene in transgenic birch was stable over the whole duration of the trial (Pasonen *et al.*, 2004). In the field trial, significant variation among the 15 transgenic lines was observed in the growth parameters as well as in parameters linked to general plant condition and leaf phenology. The variation among the lines was greatest in height, diameter, and relative growth rate. It was hypothesised that the differences among the lines could be explained by the differences in the level of sugar beet chitinase IV expression but only little support was found for that. The level of the transgene expression was not detected to have influence on the parameters related to growth or leaf phenology, but instead it had influence on the parameters that are associated with the stress status of the tree. The significant effect of the level of sugar beet chitinase IV expression on the color value and general condition of the trees, and the increased levels of red color and the lower value for general condition of the transgenic plants compared to the control plants may indicate ecophysiological stress among the transgenic trees (Pasonen *et al.*, 2008).

Long-term field and greenhouse experiments were also established in Joensuu (Finland) in 2005 in order to clarify putative environmental risks associated with GM birch (Figures 6a and b). In this field experiment, M. Keinänen and his research group have been studying potential risks related to the establishment of plantations of silver birch GM for prevention of flowering, using *Bp-FULL1::BARNASE* plants. The field performance of the plants, growth and architecture, resistance to herbivores (Figure 7), and other stresses, as well as consequences for the soil consumer community are monitored in a regular basis during the growing season. In addition, potential changes in chemical composition and expression of the antibiotic marker gene, *nptII*, are analyzed.

Figure 6 A field trial of nonflowering birches established in Joensuu (Finland) in 2005 (the field trial was established in order to study the stability and functionality of *BpFULL1::BARNASE* construct and environmental risks associated with genetic modification and nonflowering): (a) the field in summer 2005 and (b) in summer 2006

3. FUTURE ROAD MAP

3.1 Future Prospects

At the moment, research work on GM silver birch is for the most part basic, aiming to further understanding of the functioning of genes that regulate, for example, flowering, disease resistance, and lignin biosynthesis. A research consortium led by Tapio Palva at the University of Helsinki, Finland has recently established a large expressed sequence tag library from silver birch, which will be used as a basis for birch oligonucleotide array chips (M.K. Aalto and E.T. Palva, personal communication). This will undoubtedly enable further genomic studies on birch and enhance its potential as a deciduous woody model plant. In contrast to *Populus*, birch is monoecious and lines with lowered self-incompatibility have been found (Atkinson, 1992), which enables the production of homozygous lines.

Scenarios concerning the future use of GM trees vary according to region and prevailing forestry practices. In addition to the possible environmental risks and our limited ability to predict those risks, there are many other problems that will possibly hinder GM silver birches from large-scale forestry use in practice. Long rotation time of many forest tree species including silver birch pose considerable challenges for the confirmation of the long-term expression

Figure 7 In the field test of nonflowering birches, the herbivory is among the subjects studied. The larva of *Epirrita autumnata* eating a birch leaf

of introduced genes despite the fact that the expression of many transgenes would only be required in a specific tissue or at limited stage of the life cycle. Silver birch is well adapted to different latitudes and altitudes and has ecotypes that have different requirements for seasonal temperature variation. Taking the adaptation of silver birch especially to local thermal conditions into account, the use of GM silver birch in practical forestry would require a wide genetic background for the cultivated GM trees. In current research, transgenic lines are usually regenerated only from a couple of clones. Hence, it is not thoroughly known how much variation is there among the genotypes in their predisposition to genetic transformation. Furthermore, the sociological aspect of biotechnology should also be taken into account before considering the use of GM trees in forestry. It is reasonable to ask what are the main ethical views and concepts of the use of biotechnology and what kinds of public concerns, attitudes, and perceptions there are on the issue of using GM trees.

3.2 Addressing Risks and Concerns

Gene technology provides a new powerful tool for speeding up breeding of forest trees and solving problems connected to stress physiology, disease resistance, and yield and quality of the wood. On the other hand, the resolved problems may also create new problems that need to be solved before GM trees can become an integral part of our ecosystem. The potential problems associated with the use of GM birches include the changes in the consumer community caused by altered quality of the birch as a resource. Birches are important food plants for mammalian herbivores, such as moose, hare, and voles (Rousi *et al.*, 1989, 1990; Tahvanainen *et al.*, 1991), and numerous insect herbivores (Annala, 1987; Shaw, 1984; Pritinen *et al.*, 2003). Genetic modification of a plant may cause changes in the structure, function, and diversity of the community of organisms inhabiting the GM plantation. This may be due to changes in the palatability of the modified plant or, for example, due to the absence of flowers, pollen, and seeds in the transgenic plantation. Establishing plantations composed mostly or

entirely of GM trees can be expected to affect the abundance of these consumers and the species interacting with them. Furthermore, studies on life history trade-offs indicate costs of reproduction in various organisms (Roff, 1992). Thus, plants modified for prevention of reproduction can be expected to have additional resources for growth and defenses against environmental challenges, such as herbivory. Palatability of plant tissues is considered to be related with the quality and quantity of secondary metabolites in them (Hartley and Jones, 1997). Both growth rate and the level of defense may alter plant palatability for herbivores and furthermore, change the performance of herbivores and their population dynamics in a way that could cascade through the entire community. Changes in plant palatability may also affect leaf litter decomposition and nutrient mineralization in soil, thus potentially having far-reaching effects in the forest ecosystem. These aspects are currently being investigated in a field trial of young non-GM birch stands manipulated for the presence of seeds and inflorescences by the research group of M. Keinänen at the University of Joensuu, Finland. Both below- and above-ground consumer communities are sampled to reveal long-term effects cascading throughout the food webs.

3.2.1 Nontarget effects of chitinase transgenic birch

In nature, trees interact with a broad spectrum of organisms, and GM trees may have both direct and indirect effects on other species. In boreal soil ecosystems, forest trees form symbiotic associations with a number of ectomycorrhizal fungi that facilitate nutrient supply and provide protection against pathogens (Smith and Read, 1997). Moreover, beneficial mycorrhizal and saprophytic fungi contain chitin in their cell walls and may be highly sensitive to transgenic chitinases or overexpression of plants' own chitinases. The ability of transgenic birch to form ectomycorrhizae, when constitutively expressing sugar beet chitinase IV, was tested with the common ectomycorrhizal fungus, *Paxillus involutus* (Batsch) Fr. (Pasonen *et al.*, 2005). The results showed that all the transgenic birch lines were able to form normal ectomycorrhizae

containing distinctive mantles and Hartig nets, and the level of sugar beet chitinase IV expression had no influence on mycorrhizal colonization.

Below-ground food webs are composed of dynamic communities that are closely interlinked with the above-ground systems (Wardle *et al.*, 2004). While saprophytic microbes form the basis of soil decomposer food webs, soil fauna stimulate microbial activity by grazing on soil microbes and secreting N-rich excrements in the decomposing matter (Setälä, 2002). The decomposition process of the leaf litter from transgenic chitinase birch lines was studied in a field trial (Vauramo *et al.*, 2006). The mass loss of the litters was measured after 8 and 11 months of the establishment of the experiment. Mass loss of chitinase transgenic leaf litter did not differ from that of the control plants. Similarly, no differences in the fungal (litter ergosterol content) or total microbial biomass or activity between the transgenic and control plants were detected. A single transgenic line showing high chitinase expression differed significantly from the control in the mean number of nematodes. The nematode population in this litter showed distinct temporal dynamics compared to the controls, thus indirectly indicating microbial differences in the litter (Vauramo *et al.*, 2006). Kotilainen *et al.* (2005) reported a negative response of nematodes to chitinase transgenic leaf litter but a positive effect on the numbers of collembolans in a microcosm experiment.

The attractiveness of chitinase transgenic birch to two common insect herbivores, aphids (Homoptera: Aphididae) that feed on leaf fluids and to a cambium miner, *P. betulae* (Diptera: Agromyzidae) larvae of which cause an aesthetic defect to birch wood, were monitored in a field trial. In general, more aphids were found from the transgenic trees than from the control trees. A more detailed analysis of insect densities revealed that aphids were the most abundant group of insects in all trees, and the differences in the aphid densities corresponded to the differences in total insect densities (Vihervuori and Lyytikäinen-Saarenmaa, unpublished results). The variation in the occurrence of *Phytobia* larvae in the transgenic and control trees was not connected to the transgene expression but was mainly explained by plant size (Pasonen *et al.*, 2008).

3.2.2 Nontarget effects of birch genetically modified for lignin biosynthesis pathway

While genetic engineering may improve the quality or quantity of wood, lignin modifications can have potential ecological impacts by influencing the palatability of leaves to herbivores, the resistance of trees to pathogens, and the decomposition of plant residues by soil organisms (Pilate *et al.*, 2002). The effects of the modification of lignin biosynthesis pathway in birch on the feeding preferences of five common insect species that feed on birch leaves, larvae of the moths *Aethalura punctulata* (Denis and Schiffermüller), *Cleora cinctaria* (Denis and Schiffermüller), and *Trichopteryx carpinata* (Barkhausen) (Lepidoptera: Geometridae), and adults of the leaf beetles *Agelastica alni* (L.) (Coleoptera: Chrysomelidae) and *Phyllobius* spp. (Coleoptera: Curculionidae) were studied by Tiimonen *et al.* (2005). Transgenic birch lines showed decreased S/G ratio in stems and leaves. The results from the controlled feeding experiments revealed that *A. punctulata* and *C. cinctaria* showed some feeding preference to the leaves of some transgenic lines but the differences could not be directly associated to lignin modification. The other tested species did not show any preference to different types of the leaves and the relative growth rate of the tested herbivores did not vary between the transgenic and control leaves.

Fungi and bacteria that act as main primary consumers of decomposable materials in soil may be highly sensitive to changes in lignin content and composition of the decomposing plant material. The effects on decomposer subsystem can be far reaching because decomposers indirectly regulate plant growth by determining the supply of available nutrients (Wardle *et al.*, 2004). Seppänen *et al.* (2006) studied the effects of the *4CL* antisense transformation of silver birch on the interactions between transgenic birch and ectomycorrhizal fungus *P. involutus*, and the decomposition of the transgenic leaf litter. The transformation was reported to cause no marked changes in wood chemistry but to have pleiotropic effects on root biomass and morphology. Despite the disturbed root formation, the transgenic birch lines formed normal ectomycorrhizas with *P. involutus* and

were equally well colonized by the mycorrhizas *in vitro* when compared to the nontransgenic control plants. In a field trial, the decomposition of the transgenic and wild-type birch litter was equally rapid, and no marked differences were found between the transgenic lines and their controls in total microbial biomass or activity. The effects of the genetic transformation on the ergosterol content of the leaf litter were contradictory; the litter from one transgenic line had significantly higher ergosterol content, and the litters from two other transgenic lines had significantly lower ergosterol content than the litter from wild-type birch (Seppänen *et al.*, 2006).

3.2.3 Risk from gene flow

If fertile transgenic trees would be tested in long-term field trials or cultivated in plantations, transgenes could spread in an uncontrolled way via pollen and seeds to wild populations of the same or related species. For the present, ecological consequences of the spreading of transgenes are not well known. The possibility that transgenic plants would hybridize with wild-type plants of the same species, and finally introgress into native populations, is one of the most frequently mentioned threats from the use of GM plants (Conner *et al.*, 2003). Many ecological and genetic factors will finally determine how easily seeds or pollen migrate from one population to another and whether hybridization and genetic introgression occur. Gene flow and introgression from GM plants to wild-type plants have mainly been studied in *Brassica* (Rieger *et al.*, 2002; Warwick *et al.*, 2003) and other herbaceous plants (Watrud *et al.*, 2004). However, empirical data on the hybridization abilities or gene flow among GM trees is not available. Considering the relative ease of massive long-distance transport of pollen and seed of silver birch and other forest trees, broad geographic ranges and high levels of natural gene flow among populations, the release of pollen or seeds from GM trees could have further-reaching consequences than from crop plants. Furthermore, many agricultural crops are selfers while most forest trees, including silver birch, are outcrossers, and have relatively weak reproductive barriers making them relatively prone to genetic pollution.

Hence, prevention of flowering or induction of sterility would provide a solution to the problems caused by the risk of the spreading of transgenes into natural birch populations.

Douglas Fir

Santosh Misra¹, Mariana A. Vettrici¹ and John N. Owens²

¹Department of Biochemistry and Microbiology, University of Victoria, British Columbia, Canada, ²Department of Biology, University of Victoria, British Columbia, Canada

1. INTRODUCTION

1.1 History, Origin, and Distribution

The conifers are a small but ancient group of seed plants. They originated over 200 million years ago (Mya) and were a dominant form of vegetation during the Mesozoic period and were represented by many families and an unknown number of species. Presently, they are represented by only 5 to 8 families, 68 genera, and 629 species (Farjon, 1998). The number of families varies because recently some families have been combined (Cupressaceae and Taxodiaceae into the Cupressaceae) and others have been split. The commonly recognized families now and their time of origin are as follows: Podocarpaceae with 18 genera and 184 species and originating about 223 Mya; Araucariaceae with 3 genera and 41 species and originating about 215 Mya; Pinaceae with 11 genera and over 200 species and originating about 200 Mya; Cupressaceae with 28 genera and 135 species and originating about 200 Mya; Taxaceae with only 5 genera and 22 species and originating about 200 Mya; and Cephalotaxaceae with but 1 genus and 10 species and originating about 160 Mya. Conifers are predominately north temperate in distribution with the Pinaceae being strictly in the northern hemisphere and the Araucariaceae being strictly in the southern hemisphere, while

the remaining families may occur in both hemispheres with Taxaceae, Cephalotaxaceae, and Cupressaceae predominately in the northern and Podocarpaceae predominantly in the southern (Farjon, 1998).

Douglas fir (*Pseudotsuga menziesii* Mirb. Franco) is in a small genus (*Pseudotsuga*) currently thought by some to have only four species and three varieties (Farjon, 1998), or more commonly six species (Orr-Ewing, 1966; Thomas and Ching, 1968), but some authors recognize more than 10 species (Martinez, 1963). Species are native to China, Taiwan, Japan, and western North America. *P. menziesii* (Figure 1) is the most familiar and important species, having an enormous north–south range of almost 5000 km, and extending from the Pacific Coast to the eastern slope of the Rocky Mountains (Fowells, 1965) (Figure 2). It is distributed throughout most of the southwestern part of British Columbia, throughout the Pacific Northwest in the United States, and extends southward along the Rocky Mountains and dry interior regions well into Mexico at higher elevations. In British Columbia and the Pacific Northwest, Douglas fir is commonly recognized as having coastal (var. *menziesii*) and interior (var. *glauca*) varieties. It is widely planted as a commercial forest species and especially as an ornamental in many other temperate regions of the world from Europe to New Zealand.

Figure 1 Douglas fir branch and mature seed cones

1.2 Botanical Description

Douglas fir, *P. menziesii* (Mirb.) Franco (Figure 1) is a member of the family Pinaceae, the largest family of conifers. Although, most conifers have

Figure 2 Douglas fir growing at high elevations in the Rocky Mountains of Arizona

24 chromosomes, Douglas fir, as well as other *Pseudotsuga* species, has a $2n$ number of 26 (Thomas and Ching, 1968).

Pseudotsuga macrocarpa (big-cone Douglas fir) is the closest relative and is found in southern California and northern Baja California. At least four additional species have been recognized in Mexico: *Pseudotsuga flahaulti*, *Pseudotsuga guinieri* Flous, *Pseudotsuga macrolepis* Flous, and *Pseudotsuga rehderi* Flous (Martinez, 1963). However, their status as species is questionable and they may only represent extremes in ecotypic variation of *P. menziesii*. Four species are commonly recognized from China, Taiwan, and Japan: *Pseudotsuga forrestii* Craib, *Pseudotsuga japonica* Beissner, *Pseudotsuga sinensis* Dode, and *Pseudotsuga wilsoniana* Hayata (Henry and Flood, 1920).

Douglas fir withstands wide temperature ranges from -30 to 43°C , with an average range of 7 – 13°C where it grows best. Douglas fir can be found in many parts of western North America and is utilized primarily for lumber. It grows rapidly on favorable sites and is very long lived; ages in excess of 500 years are common and some exceed even 1000 years. The older trees can become very large. The largest reported grew in Washington State and measured 4.8 m in diameter and 118 m in height. For satisfactory establishment it requires more light than many of its commonly associated species including western and mountain hemlocks, western red cedar, Sitka spruce, and grand and amabilis firs. Because it always occurs in association with these more tolerant species, it rarely maintains a climax position and is generally recognized as a subclimax species. Its widespread occurrence in even-aged stands results largely from stand destruction by periodic fires, clear cutting, and insect attack or a combination of these factors. If the stands are protected from these disturbances, they would gradually be replaced by the more tolerant western hemlocks, western red cedars, and the true firs. However, its thick bark makes older Douglas fir trees fairly resistant to fires. Common insect pests are the Douglas fir beetle (*Dendroctonus* sp.) and borers (*Melanophila* sp.) that attack trees from the large pole size to maturity killing trees in small patches to very large areas. Several trunk and root rots cause extensive loss and have prevented the replanting of Douglas fir in some areas. These include fungal

species of *Fomes*, *Polyporus*, and *Poria* (Fowells, 1965).

1.3 Economic Importance

The very wide distribution and high quality of lumber derived from Douglas fir make it one of the most important economic species in western North America. The high quality of the lumber from Douglas fir is recognized internationally, and many countries are choosing to grow their own plantations. Its wood is moderately light to heavy, hard, and strong. It is used extensively in construction as beams, studs, lumber, and plywood, as well as interior and exterior finishing. It is one of the best-known softwood timber trees in the world market (Hosie, 1979). Harvest of the species is extensive and in most areas regeneration is not by natural but by planting seedlings.

1.4 Traditional Breeding: Breeding Objectives, Tools and Strategies, and Achievements

The two main objectives of Douglas fir breeding are improvement of economic value and maintenance of adaptability (Howe *et al.*, 2006). Adaptability refers to cold and drought tolerance and is usually selected for in the breeding zones. Stem volume is the main determinant of economic value, followed by stem quality and wood properties (Howe *et al.*, 2006).

Although cones are still collected from wild trees and the seed extracted and used to produce seedlings for reforestation, most Douglas fir seedlings are now derived from selected parent trees grown in clonal seed orchards. Over several decades, animal and plant breeding techniques have been adopted, modified, and applied to many forest trees. Compared to agricultural crops, forest tree breeders have had to consider unique ecological, population, and quantitative genetics issues in recurrent selection programs and deployment strategies. Tree breeders have worked with wild populations, requiring that factors such as geographic variation, seed transfer within environmentally similar zones of adaptation, and progeny testing to be taken into consideration (Yanchuk, 2003).

Genetic improvement in trees is a very slow process compared to most agricultural crops, mainly because of the long juvenile growth period, often 10–20 years for many conifers, plus the long reproductive cycle, which may take from 15 to 27 months from cone initiation to seed maturity in different species. Very briefly, the tree improvement process must begin with genetic surveys of natural populations (provenances), the collection of samples from recognized provenances to be planted in several environments to test performance of the local provenances versus others. Superior tree selection based on phenological traits in the wild from within the provenances is then done and scions are collected and grafted to suitable rootstocks. For some species, rooted cuttings may be used to bypass grafting problems that often occur. Once the breeder has assembled a large enough population of selections from the wild (usually several hundred), the progeny from these may be tested. In this way the mother tree's true genetic worth may be tested by evaluating how its offspring perform relative to other offspring from other parents. Progeny testing may have many designs and may be done across many environments and the offspring performance statistically tested. Growth, yield, and genetic gain trials are commonly used. First-generation seed orchards may be established from the originally grafted scions or advanced breeding and testing may be done from the offspring of these first-generation seed orchard trees to produce a second-generation seed orchard in which the genetic gain is higher (Yanchuk, 2003). The time required to reach this second stage may be 20 or more years, depending upon the time it takes for the species to reach reproductive maturity (Figure 3) and the length of the reproductive cycle of the species. Therefore, any techniques that may shorten this time—cultural, physiological, or molecular—would be very helpful to the breeder.

Seed orchards designed for the production of genetically improved seed for reforestation have many inherent problems. They are usually placed outside the natural range of the species to prevent or reduce pollen contamination in the wind-pollinated conifers but this may interfere with good cone or seed production. Pollen cones and seed cones may not be produced in abundance every year, some trees may be poor

Figure 3 Reproductively mature Douglas fir clonal seed orchard

cone producers most years and synchronization of pollen shedding and seed-cone receptivity may be poor. These problems have led to the development of techniques to enhance cone production; collect, extract, store, test, and apply pollen; enhance cone and seed development and survival; harvest, test, and store seeds; and germinate seeds and grow uniform healthy and hardy seedlings for reforestation.

Because reforestation requires a constant supply of high-quality economical seeds, tree improvement programs were begun in the region in the mid 1900s. Although there is a large stock of stored Douglas fir seed collected in the wild in coastal regions, this is gradually being used less. Presently about 50% of the Douglas fir seed used for reforestation comes from Class A (genetically selected and orchard-produced) seeds. As an example, in British Columbia, 32.5 million container-grown coastal Douglas fir seedlings were planted on crown land between 2002 and 2005. With a sowing factor (number of seeds sown to obtain one seedling) of 2 for high-quality seeds, this is about 20 million seeds per year. Similar requirements would be required for private and public lands in the Pacific Northwest. This would be about 200 kg of seed for each of the two regions. Seed production in Douglas fir seed orchards is generally good and there are no major problems, but management can always be improved in order to get more abundant flowering earlier and the highest possible seed-cone survival and filled seed per cone. For good forest genetics, breeding, and seed orchard management, it is important to have a

basic knowledge of the reproductive cycle and the reproductive biology of the species. This is equally important for those doing research in molecular biology, especially if they are directing or doing their own specimen collection and preparation. They must recognize various sporophyte and gametophyte structures and the various stages of their development.

Conventional seed orchards are managed to produce large amounts of superior seeds, they can remain productive over decades and are highly cost effective (Howe *et al.*, 2006). The disadvantages of seed orchards are that genetic gains and financial returns are delayed because there is a long lag (10–15 years) between orchard establishment and quantitative production of improved seed (Howe *et al.*, 2006). An alternative that offers rapid genetic gains and lower costs is the miniaturized seed orchard (MSO). MSOs require less land, can be subjected to controlled pollination, management costs are lower because the crowns are closer to the ground, and seed harvesting may be possible 3 years after grafting (Howe *et al.*, 2006). Vegetative propagation is the strategy of choice for significantly reducing time consumption.

The achievement of conventional orchards is that they are now producing surplus seed and companies in the Pacific Northwest are harvesting and deploying seed from only the best parents.

1.4.1 Reproductive cycle

The wide distribution of Douglas fir makes it difficult to describe the phenology of the reproductive cycle. The occurrence of particular events is strongly affected by temperature and may vary by more than a month in individuals at the extremes of the distribution and by a few weeks in the same individual in different years. Consequently, the phenology given (Figure 3) is that of coastal Douglas fir growing at moderate elevations in the center of its range (Figure 4). Even though the phenology will vary with geographical distribution, the sequence and details of reproductive development remain the same and a single general description of the reproductive cycle is valid (Allen and Owens, 1972).

The reproductive cycle of Douglas fir is similar to most non-*Pinus* members of the Pinaceae in

Figure 4 Distribution of Douglas fir

that it extends over about 17 months from cone-bud initiation and differentiation to seed cone and seed maturity. In some conifers such as *Pinus*, there is 1 year between pollination and fertilization, which increases the reproductive cycle to just over 2 years from cone initiation in the late summer and autumn to seed maturity (Allen and Owens, 1972).

1.4.2 Seasonal growth, bud initiation, and bud development

Seasonal growth in conifers is commonly thought to begin when vegetative buds burst in the spring, about mid May in coastal regions. However, considerable growth and development occur within the vegetative buds before bud burst (flushing). It is this growth and development that causes flushing. The vegetative buds of Douglas fir are completely preformed before winter dormancy

Figure 5 Dissected dormant vegetative bud of Douglas fir (the bud scales enclose the green bud bearing the leaf primordia)

and all leaf primordia for the next season's growth are present (Figure 5).

Vegetative buds resume growth about the last week of March. Cell divisions and cell elongation occurs in the shoot axis and leaf primordia causing the buds to swell. In early April, lateral bud apices are initiated in the axils of some of the leaf primordia. The axil is just distal (above) the point where the leaf joins the stem. These axillary or lateral bud apices initiate bud scales and for about 10 weeks during which time all lateral buds appear the same except for slight differences in size and in their position along the shoot (Figure 6). Potential pollen-cone buds are usually near the base of the shoot, whereas potential vegetative and seed-cone buds are more distal. The terminal buds remain vegetative (Figure 7). After about 10 weeks of bud-scale initiation, the lateral buds begin to differentiate into pollen-cone, seed-cone,

Figure 6 Diagram showing the initiation and pathways of axillary bud development in a vegetative bud on a lateral branch of a sexually mature Douglas fir

or vegetative buds. Pollen-cone buds initiate all of their microsporophylls, seed-cone buds all of their bracts and ovuliferous scales, and vegetative buds all of their leaf primordia before winter dormancy begins late in the fall of the year of lateral bud initiation. Some buds stop development after most bud scales have been initiated and remain as undeveloped latent buds (Figure 7). Vegetative and cone buds are completely preformed and recognizable before winter dormancy, which begins about November in coastal Douglas fir (Figure 7) (Owens and Smith, 1964; Owens, 1969).

Methods for cone induction in young trees in seed orchards have been developed in order to increase cone for breeding purposes and seed production for reforestation. Various cultural techniques have successfully been used including

root pruning, girdling, and fertilizer treatments often in combination with the application of gibberellin A4/7 (Ross *et al.*, 1985; Owens *et al.*, 1986).

1.4.3 Postdormancy cone development and pollination

After winter dormancy, pollen-cone and seed-cone buds resume growth usually early in March, a few weeks before vegetative buds on the same branch. Cone buds develop while still enclosed within the bud scales and pollen-cone buds form pollen and seed-cone buds form ovules. Meiosis occurs in pollen-cone buds late in March soon after they break dormancy and pollen is mature usually by mid April (Owens and Molder, 1971). Seed-cone buds break dormancy at about the same time as pollen-cone buds and form ovules, but meiosis within the ovules does not occur until the time of pollination. Pollen-cone and seed-cone buds burst usually in mid April and pollination occurs during about a 2-week period (Figure 8). At pollination, the pollen cones are pendant, they dry and the microsporangia split open releasing the pollen. At pollination, the seed-cone buds are erect with the long trident bracts are reflexed allowing pollen to enter the cone and pass down to the two ovules that develop on each ovuliferous scale (Figure 9) (Owens *et al.*, 1981).

There are some unusual features of Douglas fir reproduction that make it very different and sometimes more difficult for study and experiments than the pines. Douglas fir pollen is nonsaccate, meaning it has no air bladders, which are the floatation devices for pollen of many other conifers (i.e., pines, spruce, and true firs) (Figure 10) (Owens and Simpson, 1986). The pollen when shed contains less than 10% water content and appears indented due to the drying, and in this dry state it can be stored at -20°C in air-tight containers for many months or years. Mature pollen has five cells as shown with 4',6-diamidino-2-phenylindole (DAPI) staining (Figure 11), but contains no sperm cells—these form by division of the generative cell after pollen tube formation. In contrast to most conifers, when Douglas fir pollen germinates it does not immediately form a pollen tube; so, standard germination tests for viability cannot be used. Tests such as respiration

Figure 7 Branch from a sexually mature Douglas fir showing the usual position, size, color, and shape of vegetative lateral, pollen-cone, seed-cone, and latent buds

and electrolyte leakage must be used (Webber and Painter, 1996).

1.4.4 Pollination mechanisms

The pollination mechanism is related to the pollen and ovule structure and Douglas fir (Owens *et al.*, 1981, 1985) and larch (*Larix*) (Owens *et al.*, 1994) are unique in this regard among the conifers (Figure 12). Pollen carried by wind enters the erect and receptive seed cones and moves over the smooth cone surfaces down to the base of the ovuliferous scale, where the two ovules are located. The ovules have an inverted globose tip with a slitlike opening (the micropyle) and many stigmatic hairs to which the pollen adheres. The stigmatic tips capture pollen for several days; then the tip grows inward, engulfing the stigmatic hairs, and the attached pollen into the micropyle (Figure 13). Many other conifers, such as the pines and spruces, have ovules with an inverted two-pronged tip. A pollination drop is secreted by the ovule and emerges from a large oval-shaped micropyle between the two prongs. The

pollen grains, which are saccate, adhere to the sticky prongs and are picked up by the pollination drop. Because of the air bladders the pollen grains float up through the micropyle and into the micropylar canal of the ovule. Viable pollen grains taken into the ovules with the pollination drop germinate within a day or two and pollen tubes quickly form and grow into the nucellus at which time the sperms are formed. Because of this pollination-drop mechanism, pollen germination is a rather simple process in pines, spruce, and true firs (Webber and Painter, 1996). Five pollination mechanisms are recognized in the conifers (Owens *et al.*, 1998) and developmental and molecular studies have been made for conifer pollen tube growth and development (Fernando *et al.*, 2000).

1.4.5 Gamete structure, fertilization, and cytoplasmic inheritance

In Douglas fir, pollen grains that have been engulfed into the moist ovule germinate and elongate down the micropylar canal for about 9

Figure 8 The reproductive cycle of coastal Douglas fir

weeks, until they reach the tip of the nucellus where the elongated pollen forms a narrow pollen tube that penetrates the nucellus (Takaso and Owens, 1994, 1996). During pollen tube growth, the generative cell within each pollen tube forms two equal-sized sperm nuclei that remain within the generative cell cytoplasm (Owens and Morris, 1990, 1991; Fernando *et al.*, 1997, 1998, 2001). The

development and molecular regulation of conifer pollen tube growth are reviewed by Fernando *et al.* (2001). During pollen elongation and pollen tube growth, the megagametophyte tissue in each ovule forms about 2000 cells, 2–6 of which are egg cells. The eggs are large complex cells in which mitochondria aggregate around the egg nucleus and plastids are transformed into large

Figure 9 Douglas fir pollen cones and seed cones at pollination in April

Figure 11 Germinated Douglas fir pollen stained with DAPI (five cells)

dysfunctional vesicular structures, often called large inclusions (Singh, 1978). Each egg is enclosed by an archegonial jacket layer with several neck cells at the tip facing the micropylar canal. Each pollen tube grows to a separate archegonium, penetrates the neck cells, and bursts into the egg cell releasing the two sperms, generative cell cytoplasm, and other pollen tube contents into the egg cell. Variable numbers of eggs may be fertilized in each ovule depending upon the number of pollen tubes growing through the nucellus (Figure 14).

The leading sperm moves toward the egg nucleus and the second sperm trails behind. Between the two sperms, the generative cell cytoplasm, with its abundant paternal mitochondria and plastids, also moves toward the egg nucleus. The leading sperm fuses with the egg nucleus and the trailing sperm degenerates. The paternal mitochondria and plastids intermingle with the abundant maternal mitochondria surrounding the egg nucleus forming the neocyttoplasm of the zygote. Thus, most zygote mitochondria (about 90%) and all plastids are paternal in origin. This type of cytoplasmic inheritance, in which mitochondria are biparentally inherited and plastids paternally inherited, is found in all of the Pinaceae that have been studied thus far (Owens and Morris, 1990, 1991; Morgensen, 1996). The paternal inheritance of chloroplast DNA for Douglas fir has been confirmed using restriction

Figure 10 Scanning electron micrograph of mature, dry Douglas fir pollen

Figure 12 The five pollination mechanisms found in conifers

fragment length polymorphism techniques (Neale *et al.*, 1986). The type of cytoplasmic inheritance varies among conifers with members of the Podocarpaceae, Araucariaceae, and Taxaceae being similar to that of the Pinaceae but members of the Cupressaceae having paternal mitochondrial and plastid inheritance (Bruns and Owens, 2000). The type of cytoplasmic inheritance that occurs in a species can be traced back to the structure and development of pollen, sperms, archegonia, and eggs (Bruns and Owens, 2000), and the fate of the pollen tube and egg organelles at fertilization (Owens and Morris, 1990, 1991; Morgensen, 1996).

Figure 13 Scanning electron micrograph of the ovuliferous scale of Douglas fir at pollination showing the stigmatic tips with pollen attached

1.4.6 Embryo development

Embryo development begins immediately after fertilization and in conifers can be divided into four stages: proembryo, early embryo, mid embryo, and late embryo (Allen, 1943, 1946, 1947a, b; Allen and Owens, 1972; Owens *et al.*, 1993). The proembryo in most conifers includes the stages of development from the zygote (Figure 14) to the 16-cell proembryo (Figure 14), but in Douglas fir proembryo development stops at the 12-cell proembryo and there is no rosette (dysfunctional suspensor) tier. The early embryo begins when the primary suspensors elongate pushing the apical tier of cells through the archegonial jacket and into the megagametophyte tissue (Figure 14) and includes the elongation of the suspensor system and the formation of a multicellular, club-shaped embryo (Figure 14). The mid embryo includes the rapid enlargement of the embryo and the formation of the root or radicle, shoot, and cotyledons. The late embryo includes the completion of development of these structures and their maturation.

Most conifers, such as the pines, have two types of polyembryony, a process by which several embryos can develop within one ovule. Simple (or archegonial) polyembryony occurs when more than one egg is fertilized in an ovule and each fertilized egg may develop into an embryo. Douglas fir, with four to six eggs per megagametophyte, usually has simple polyembryony if more than one pollen grain enters the ovule. But the second type of polyembryony,

Figure 14 (a)–(h) Diagram showing fertilization, cytoplasmic inheritance, and the proembryo and early embryo stages of development in Douglas fir (sperms and paternal organelles are shown in blue, egg nucleus and maternal organelles are shown in red, and embryo cells are shown in yellow)

cleavage polyembryony, is absent in Douglas fir. In cleavage polyembryony, after the suspensors have pushed the apical tier into the megagametophyte, the apical tier separates into four files of cells and each file can develop into a separate early embryo. This multiplies the number of possible early embryos by four. In simple polyembryony, all of the embryos are genetically different leading to competition among the early embryos. In cleavage polyembryony, there may be several groups of embryos (equal to the number of fertilized eggs) each group with four genetically identical embryos. The advantage of simple polyembryony is obvious but that for cleavage polyembryony is not. Perhaps creating a larger number of genetically identical embryos in an ovule may simply increase the chance for one to survive. However, during early embryo development all but one of the embryos abort leaving usually only one embryo in the seed.

Although cleavage polyembryony does not occur in *Pseudotsuga* and *Picea*, cells in the four files may contribute equally to the embryo, or two files or sometimes only one file divide and elongate more than the others and grow over the others. But, unlike cleavage polyembryony these files do not separate. This has been called delayed, incomplete, or incipient cleavage and is an intermediate form of development between cleavage and no cleavage (Schopf, 1943). The causes for cleavage and incomplete cleavage are not known and the evolutionary relationship is unsettled.

In Douglas fir fertilization occurs at the beginning of June and proembryo development takes place during the next 1–2 weeks within the archegonia. This is followed by another 2 weeks of early embryo development then 2 weeks of mid embryo development. By mid July embryos are small but easily seen in dissected ovules, tissue regions can be recognized within the embryos, and storage products have started to form. Late embryo development begins about mid July and continues until the end of August when embryos are mature (Figures 8, 15, and 16). At first the late embryo fits tightly within the corrosion cavity of the megagametophyte (Figure 16), but as the embryo matures and dehydrates, space forms between them.

Storage products begin to accumulate in the megagametophyte at fertilization and in the embryo at about the mid embryo stage. The

Figure 15 Mature Douglas fir seed

Figure 16 Mature seed from Douglas fir that has been sliced in half longitudinally showing a portion of the seed wing attached to the three-layered seed coat (the seed is hydrated so the diploid embryo fits tightly within the haploid megagametophyte tissue; cotyledons, embryonic root and shoot, shoot apex, and suspensor are visible)

megagametophyte is a maternally derived, haploid tissue. Megagametophyte cells are the primary food storage tissue supplying the developing embryo and at seed germination. Formation of the storage material is by conversion of soluble substances that are present in the megagametophyte at fertilization into complex insoluble storage products (mostly lipids and proteins) in the megagametophyte and embryo in the mature seed. At fertilization megagametophyte cells are small cells with thin walls and contain several large vacuoles, plastids with starch grains, and a few small protein bodies. During early embryo development, some of the starch is broken down, protein bodies enlarge, and become more abundant and many small lipid bodies form. During mid and late embryo development and embryo and seed maturation, protein bodies become very large and more abundant and lipid bodies almost fill the megagametophyte cells (Figure 17a). Most embryo cells also accumulate smaller protein and lipid bodies that fill most of the cells, but some cells of the embryonic root store starch and other specialized cells, such as secretory cells (Figure 17b), and meristematic cells of the shoot apex and procambium, have few storage products.

During embryo development there is a transfer of nutrients from the megagametophyte to the

embryo and a general conversion of soluble reserves to insoluble reserves, mostly as lipid and protein bodies. The dry weight of the megagametophytes more than doubles from the time of fertilization until embryo maturity, at which time embryo dry weight is only about 10% of megagametophyte dry weight. Soluble sugars decrease in megagametophytes and embryos during development. The small amounts of lipids present in the megagametophyte at fertilization become abundant by 6 weeks after fertilization and dominate the storage products in the mature seeds (Figure 17a). In mature Douglas fir seeds, 90% of the lipids are in the megagametophyte and 10% in the embryo. In the megagametophyte and embryo of mature seeds, lipids make up about 60% and 45% of the dry weight, respectively, and proteins make up about 16% and 11% of the dry weight, respectively. At seed maturity, soluble sugars make up only 2% and 3% of the dry weights of megagametophyte and embryos, respectively. These proportions of seed storage product and the abundance of lipid and protein bodies appear to be typical for the *Pinaceae*.

The seed coat begins to differentiate about the time of fertilization and is complete by late August. The seed wing develops from the ovuliferous scale but fuses with the seed coat (Figure 15). Seed cones begin to dry and turn brown by late August, then

Figure 17 Electron micrographs of lipid and protein bodies as storage products in the mature megagametophyte (a) and mature embryo (b)

open and release seeds in September (Allen and Owens, 1972).

The entire reproductive cycle, from cone-bud differentiation until seed and cone maturity, takes about 17 months and includes one winter dormant period. The time from pollination to cone maturity takes only about 6 months. However, the entire reproductive cycle must be considered because many things can go wrong during the first 11 months that may reduce cone and seed production (Owens and Morris, 1991).

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

The major limitation of conventional breeding is the length of the reproductive cycle. In addition, genetic gains per single trait are decreased as more traits are incorporated into the breeding program and very little is known about the genetics of real traits (Howe *et al.*, 2006). Somatic embryogenesis is more acceptable than transgenic breeding, because it eliminates the need for regulation and because public perception is less negative. It is also possible to capture multiple traits in a few individuals, and these elite individuals can be easily propagated via somatic embryogenesis. A limitation of somatic embryogenesis is that the most successful protocols require embryogenic tissues for induction and these tissues are only available for a limited time. New protocols involve callus induction from mature tissues and seedling regeneration via organogenesis. Another limitation is that once new hybrids are generated, field testing may take up to 20 years before the new genotypes are characterized. So, is there a need for transgenic Douglas fir? A few authors concur that genes conferring insect and fungal resistance, and reproductive sterility would be important candidates for transgenic approaches (Strauss *et al.*, 1995; Prudham, 2003; Howe *et al.*, 2006). The gypsy moth and sudden oak death, caused by *Phytophthora ramorum*, are notable future threats to Douglas fir (Howe *et al.*, 2006).

2. DEVELOPMENT OF TRANSGENIC DOUGLAS FIR

With Douglas fir, as with the majority of other conifers, transformation is still in its infancy, with

experiments focusing on optimizing protocols to obtain stable and numerous transformants. A sense of urgency for developing and deploying transgenics does not exist due to the severe public dissent and the success of somatic embryogenesis, which permits production of superior trees from the natural gene pool and results in multiple gains. Clonal forestry via somatic embryogenesis offers 40–60% genetic gain in volume, disease resistance, and wood quality and permits deployment of the next generation in 1.5 years (Sutton, 2002). In open-pollinated seed orchards, the genetic gain is only 13% and the next generation is deployable in 12 years (Sutton, 2002).

The initial view that conifers were not hosts of *Agrobacterium* (Ellis *et al.*, 1989) may have contributed to the lag in technology and caused the early investigators to concentrate their efforts on electroporation and particle bombardment for the production of transgenic conifers. Although tissues and cells have been transformed via *Agrobacterium*, electroporation, and particle bombardment, the single reference to a transgenic Douglas fir is a personal communication from Howe *et al.* (2006) stating that a transgenic Douglas fir was maintained up to 3 years of age. There are no examples of *in planta* transformation, that is, co-cultivation of germinating seed or female cones with *Agrobacterium*. The following is a compilation of all the work that has been done to introduce transgenes into Douglas fir tissues. It will serve as an informative guide and resource for those wishing to make advances in transforming and regenerating Douglas fir.

2.1 Donor Genes, Methods, Selection of Transformed Tissue, and Testing

Dandekar *et al.* (1987) were the first to transform Douglas fir tissue, using two strains of *Agrobacterium* to deliver kanamycin resistance to micropropagated shoots and seedlings. The bacterial aminoglycoside phosphotransferase (*APH(3')II*) gene, conferring kanamycin resistance, was co-integrated into the pTiA6 *Agrobacterium tumefaciens* plasmid by homologous recombination. The resulting strains were AtK12X562E, containing the pCGN562 cosmid with the (*APH(3')II*) gene under control of the octopine synthase promoter and 3'

polyadenylation site; and AtK12X167 containing the pCGN167 plasmid with the (*APH(3')II*) gene under control of the cauliflower mosaic virus (CaMV) 35S promoter. As a result of recombination, two copies of the (*APH(3')II*) chimeric gene were inserted in tandem in the pCGN562 cosmid with corresponding right and left borders. The micropropagated shoots and seedlings were inoculated with *Agrobacterium*. Tumors were observed within 5–6 weeks near the base of the shoots and within 9–10 weeks near the hypocotyls of seedlings. Tumor weight was significantly greater on seedlings than on shoots, and strain K12X562E caused 20% of shoots and 15% of seedlings to develop tumors, while strain K12X167 resulted in tumors on 5% of the shoots and 10% of the seedlings. This transformation efficiency may be partly explained by the activity of the two promoters (Dandekar *et al.*, 1987). Selection of transformed tissues was carried out by excising the tumors and culturing on phytohormone-free medium containing 500 $\mu\text{g ml}^{-1}$ carbenicillin. The tumors grew rapidly for 8–10 weeks, then growth decreased and the tumor deteriorated. Neomycin phosphotransferase activity was assayed by detection of radiolabeled phosphorylated kanamycin when ^{32}P -ATP was used as a substrate. A radiolabeled product corresponding, in size, to product from *Escherichia coli* carrying (*APH(3')II*) was detected in transformed tissues, but not in untransformed tissues. Octopine was detected in all tumors by high-voltage paper electrophoresis. To further test the stability of the transformation, Southern analysis was performed with an internal fragment of the transfer-DNA as a probe, and hybridization was seen with all tumor tissues but not in untransformed tissues.

In a further attempt to identify *Agrobacterium* strains that transform conifers at high frequencies, Ellis *et al.* (1989) screened 36 *A. tumefaciens* strains and 1 *A. rhizogenes* strain. The initial screen on white spruce resulted in the selection of 14 strains that were later used to transform Douglas fir, Sitka spruce, and Engelmann spruce. Two binary vector systems were employed independently to assess the integration and expression of kanamycin resistance and luciferase activity. The vector pEND4K contained the *neomycin phosphotransferase* (*nptII*) gene under control of the nopaline synthase promoter and terminator sequences. The vector pLUX2 containing the

chimeric firefly luciferase gene from pDO432 was derived from pEND4K by replacing *nptII* with *LUX2*. *Agrobacterium* was inoculated into 6-month-old seedlings by piercing the stem five times with a 26-gauge hypodermic needle that was dipped in *Agrobacterium*, or by making a slice into the stem so that a flap of tissue remained attached, and placing *Agrobacterium* on the cut surface and pressing the flap against the stem. These procedures were repeated so that each seedling received 10 inoculations, 5 inoculations on stem tissue formed prior to flushing (old growth) and 5 inoculations on stem tissue formed during flushing (new growth). It was found that the slice method did not increase the frequency of infection. Gall formation was assessed visually and galls were removed for opine analysis 5 months after inoculation. *Agrobacterium* was eliminated from the galls by surface sterilizing the galls followed by incubation on hormone-free medium containing 250 $\mu\text{g ml}^{-1}$ cefotaxime and 500 $\mu\text{g ml}^{-1}$ carbenicillin for 2 months. Resistance to kanamycin was tested by transferring these galls to medium containing 50 $\mu\text{g ml}^{-1}$ kanamycin. Luciferase activity was assessed by placing the galls void of bacteria in assay buffer containing 1 mM D-luciferin and recording luminescence. Interestingly, it was found that galls on Douglas fir formed with equal frequency in old and new growth, while in Engelmann spruce and Sitka spruce less than 10% of galls were present on old growth. Also, Douglas fir galls were light brown and friable while spruce galls were green and nodular. The relative frequency of gall formation was visibly higher on Douglas fir than on the other species tested. This report shows that several different *Agrobacterium* strains are capable of infecting Douglas fir, therefore confirming that this method of transformation will be effective. The top five wildtype strains were C3/74, K6/75, B2/74, 40, and I10/75, while the disarmed strain A281 carrying the supervirulence plasmid pTiBo542 showed moderate efficiency of transformation. Luciferase activity was recorded in galls derived from Douglas fir and this indicates that the agropine synthase and nopaline synthase promoters are functional in this species.

Stomp *et al.* (1989) analyzed the effect of *Agrobacterium* strains from a different point of view. Four-month-old seedlings were inoculated by stabbing with a blade that had been dipped

overnight in *Agrobacterium*. The seedlings were assessed visually for gall formation, 8–12 weeks after inoculation, and opine production was confirmed. However, a year after inoculation, the researchers found that the galls had not enlarged but had dried up and sloughed off. Only 21 of 27 galls remained in Douglas fir, while 200 of 472 galls remained and 30 new galls appeared over all species tested. In further work with *Pinus* species, callus cultures could not be established from galls, and statistical analysis of the ability of various *Agrobacterium* species to infect hosts revealed that there is host-pathogen specificity. The extent of stem woodiness and plant age appeared to be inversely proportional to the frequency of gall formation. Stomp *et al.* (1989) also hypothesized that plant defense mechanisms or regulation of the phytohormones produced in the transformed tissues enabled pines to overcome infection and inhibit chronic gall formation.

In the single example involving electroporation, Gupta *et al.* (1988) established that embryogenic suspensor masses and then somatic embryos could be regenerated from Douglas fir protoplasts. They then transformed protoplasts with luciferase by electroporation. It was found that electroporation decreased plasmid viability from 90% to 45–55%. Luciferase activity was detectable up to 36 h postelectroporation. One inference that could be drawn from this study is that transformation of protoplasts followed by regeneration of plantlets via embryonal suspensor masses could be an alternative to *Agrobacterium*-mediated transformation.

To identify a system of transformation that would also permit regeneration in Douglas fir, Goldfarb *et al.* (1991) studied the effect of six variables on delivery and expression of foreign DNA using microprojectile bombardment. This method was chosen because it had resulted in stable transformation in a few angiosperms, and there were no reports of stably transformed conifer plants via *Agrobacterium* or electroporation. Goldfarb *et al.* (1991) germinated Douglas fir seeds in vermiculite in open trays and collected cotyledons when they emerged from the seed coat and began expanding but before the first true leaves started to elongate. The cotyledons were cut into 10-mm slices and placed on callus-forming medium (2.5 μ M 2,4-dichlorophenoxyacetic acid (2,4-D), 0.5 μ M benzyladenine (BA)) for 7–9 days. The plasmid PTVBTGUS containing the

GUS (β -glucuronidase) gene under control of the CaMV 35S promoter and the *NOS* terminator was precipitated onto gold particles that were bombarded onto the prepared cotyledons. Transient gene expression was assessed 1- or 2-day postbombardment by incubating the cotyledons overnight in GUS histochemical substrate buffer, and measuring the number of blue loci. This number gave the minimum estimate of cells with activity. When the time on induction medium was modulated between 3 and 14 days, it was found that the number of GUS-expressing loci was highest when the cotyledons were cultured at least 7 days prior to bombardment. For example, an average of 0.6 loci per cotyledon were observed after 3 days, but after 7 days an average of 5.9 loci per cotyledon were observed. It was also noted that after 7, 9, or 12 days, 90% of cotyledons had at least one locus, while only 40% of cotyledons had one locus after 3 days. Another variable tested was cytokinin pulse, which is known to induce adventitious bud formation. Cotyledonary whorls were immersed in 400 μ M BA for 2 h and then placed on phytohormone-free callus-forming medium. Bombardment after 7–14 days of pulsing resulted in loci in more than 99% of cotyledons. Multiple bombardments, seedling variability, and bombardment variability did not have a significant effect on the number of loci. To estimate the efficiency of transient expression, the number of loci on each cotyledon was counted, the cotyledon was sectioned on a freezing microtome and the number of gold particles was counted microscopically. It was found that only 0.006% of particles reaching the cotyledon were expressed. Exposing the tissues to auxin and cytokinin prior to treatment was critical for increasing the number of cells expressing the transgene and this could be attributed to the stimulation of cell division and the stabilizing effect it has on stable incorporation of foreign DNA (Goldfarb *et al.*, 1991). In Douglas fir, cell division is induced approximately 4 days after exposure to cytokinin, or auxin and cytokinin (Goldfarb *et al.*, 1991). It was concluded that biolistics is a potential technology for producing transgenic plantlets, because cotyledons can form multiple adventitious buds and shoots.

A further improvement in transgene expression may be achieved by using endogenous promoters. After studying various promoters and transgene expression in *Populus*, Ahuja (2000) concluded

that promoters cloned from plants or trees are less prone to methylation and silencing. Chatthai *et al.* (2004a) compared the ability of the CaMV 35S promoter with the Douglas fir metallothioneinlike gene promoter (pMTP) to drive the expression of GUS in Douglas fir tissues. In the Clontech pBI221 vector employed in this work, the *uidA* (β -glucuronidase) gene was under control of the CaMV 35S promoter and the NOS terminator. To create the pMTP0.9-GUS construct, the CaMV 35S promoter was excised out of the pBI221 vector and the Douglas fir pMTP was cloned in its place. These vectors were precipitated onto gold particles and the DNA was delivered to Douglas fir megagametophytes, immature zygotic embryos, and somatic embryos. GUS activity was measured 2-day postbombardment by counting the number of blue loci after incubation in GUS histochemical buffer. Megagametophytes and zygotic embryos bombarded with pMTP0.9-GUS showed two to three times more loci than those bombarded with pBI221, and there was no difference in expression levels in somatic embryos. Constructs with a series of promoter deletions revealed that expression was reduced by 50% when more than half of the promoter sequence was deleted, and this was attributed to the loss of the three ethylene-responsive elements present in the intact promoter.

In similar effort to the one described above, Forward *et al.* (2002) compared GUS activity when either the CaMV 35S promoter or the Douglas fir BiP promoter controlled GUS expression. The same pBI221 vector was utilized and the PmBiP (*P. menziesii* luminal binding protein) promoter replaced the CaMV 35S promoter region to make the test construct. Biolistic transformation of germinating Douglas fir zygotic embryos and counting the number of blue loci resulted in five- to sixfold higher expression when the Douglas fir BiP promoter was used. An unusual effect observed when *Arabidopsis* was transformed, was that expression was significantly higher when approximately 1000 bp were deleted from the PmBiP promoter sequence. Expression was increased in the entire plant and it was additionally observed in vascular tissue, lateral roots, and root tips (Forward *et al.*, 2002). This was attributed to the elimination of a putative negative regulatory region. The work with *Arabidopsis* also showed that this promoter is inducible by wounding.

A variation to the theme of endogenous promoters is tissue specificity. Chatthai *et al.* (2004b) showed that the Douglas fir 2S seed storage protein promoter (p2SSP) is capable of driving GUS expression in developing Douglas fir megagametophytes and mid-cotyledonary zygotic embryos. Because stable transformation in conifers was not feasible at the time, the p2SSP-GUS construct was transformed into tobacco seeds via *Agrobacterium*. GUS expression was observed in embryos and endosperm but not in the embryogenic radicle or root tip. When 2-week-old T₁ seedlings were analyzed, no GUS activity was detected in leaves, stems, or roots although stable integration was confirmed by polymerase chain reaction (PCR) and Southern blot analysis. These studies indicate that gene-regulating mechanisms are conserved among species that are evolutionarily distant to conifers, e.g., angiosperms. The angiosperm species serves as a useful model system for analyzing the function and regulatory mechanisms of Douglas fir genes.

2.2 Specific Regulatory Methods

The planting of transgenic trees involves applying for permits from the appropriate agency, and obtaining deregulated status. In the United States, the Animal and Plant Health Inspection Service (APHIS) regulates transgenic plants that have the potential to be plant pests, while the Environmental Protection Agency (EPA) regulates transgenic plants that produce a pesticidal substance (Strauss *et al.*, 1995). In Canada, the Canadian Food Inspection Agency regulates transgenic trees and confinement conditions are always necessary. Internationally, the Organization of Economic Cooperation and Development includes member countries Belgium, Canada, Finland, France, New Zealand, Norway, Portugal, Spain, and Sweden. In most other countries, regulation occurs at the national level.

3. FUTURE ROAD MAP

3.1 Expected Products

The benefits of deploying transgenic trees must greatly outweigh the costs of production (van

Frankenhuyzen and Beardmore, 2004; Howe *et al.*, 2006). It is evident that Douglas fir has enough genetic diversity to withstand the pests and diseases it has encountered. A niche for transgenic breeding includes resistance to Swiss needle cast, *Rhabdocline* needle cast, *Armillaria* root rot, *Phellinus* root rot; and, the exotics, gypsy moth (*Lymantria dispar*), and sudden oak death fungus, *P. ramorum* (Howe *et al.*, 2006). The insect toxin gene of *Bacillus thuringiensis* is of interest for general insect resistance, and the use of synthetic *cry* genes with host-specific codon bias was shown to increase the effectiveness of resistance (van Frankenhuyzen and Beardmore, 2004). Broad-spectrum antimicrobial peptides have been used to successfully engineer resistance to a range of fungal and bacterial diseases in angiosperm species (Osusky *et al.*, 2004). The benefit of engineering trees for resistance against a multitude of pathogens is that rare or elite genotypes will not be exterminated by disease. The Ponericins of the ant *Pachycondyla goeldii* were shown to combine antibacterial and insecticidal activities. Identification of a peptide with antifungal and insecticidal properties that are pertinent to Douglas fir would find applications in tree improvement.

Because tree value is predominantly determined by stem volume (Howe *et al.*, 2006), the identification of a gene or set of genes responsible for rapid, dense growth would classify these as candidates for genetic engineering.

Many authors agree that reproductive sterility is the best solution for the containment of transgenes (Strauss *et al.*, 1995; Ahuja, 2000; Tang and Newton, 2003; Poupin and Arce-Johnson, 2005). Research is still needed on the methods of cloning sterility and the identification of naturally occurring sterile trees that may be cloned. A unique and potentially beneficial aspect of sterile trees is that wood production will increase when no energy or nutrients are invested in cone and pollen production (Strauss *et al.*, 1995).

3.2 Risks and Concerns

The major risks associated with transgenic forest trees are invasive escape and vertical gene flow, horizontal gene transfer and undesirable effects on nontarget organisms and ecosystem processes,

and detrimental effects on transgenic trees due to the instability of transgene expression (van Frankenhuyzen and Beardmore, 2004). Invasive escape and vertical gene flow (transfer to wild relatives) are thought to result in weediness of a transgenic species over endogenous or native species. A greater risk of spread exists with transgenic trees than with crops because there is a higher likelihood that the trees will be more closely related to wild trees (Prudham, 2003; Poupin and Arce-Johnson, 2005). Finally, public concern about the release of transgenics is a major impediment. These concerns can be alleviated with time as more research and data will increase our understanding of risks. A variation to the theme of endogenous promoters is tissue specificity.

3.3 Expected Technologies

Somatic embryogenesis of conifers is currently the most efficient and advanced technology for producing superior trees. Additionally, it is suited to transgenics because rapidly dividing cells of embryogenic tissue are most easily transformed and sufficient material is available (Wenck *et al.*, 1999; Klimaszewska *et al.*, 2001). Wenck *et al.* (1999) increased the efficiency of transformation by adding additional copies of the virulence genes to the *Agrobacterium*. *Agrobacterium*-mediated transformation and regeneration of plantlets from rapidly dividing somatic embryos were successful with larch, pine, and several species of spruce (Wenck *et al.*, 1999; Klimaszewska *et al.*, 2001). The combination of elite genotypes that are being produced by somatic embryogenesis and transformation with desirable traits is a promising alternative for Douglas fir. Further experimentation is necessary with Douglas fir to establish transformation and tree regeneration as common techniques and then to start producing and testing transgenic trees of commercial value. Identification of endogenous promoters that will improve expression and stability of transgenes will make transgenic tree breeding a more realistic goal.

Another option for producing transgenic trees is via *in vitro* fertilization with transgenic pollen. Pollen transformation is a proven technology in alfalfa and the process will be identical in conifers. Labor and protocol optimization will not be

required and this will lead to significant savings of time and resources.

It is also expected that methods will be sought to achieve controlled gene expression, i.e., herbicide tolerance is only necessary during the first 2 years while plantlets establish themselves (Ahuja, 2000). Again, endogenous and inducible promoters will have a key role.

One potential application (Table 1) of transient expression, as seen with particle bombardment, is the transient induction of somatic embryogenesis from the mature tissues of rare or elite genotypes. Initiation of somatic embryogenesis is still challenging and alternative technologies are necessary to keep up with the increasing demand for wood products. The Douglas fir *LEAFY COTYLEDON1* (*LEC1*) gene (Vetrici and

Misra, 2005) is homologous to the *Arabidopsis thaliana* *LEC1* gene. AtLEC1 is a transcription factor that activates the transcription of genes required for normal embryo development. It specifies embryonic organ identity, suppresses the embryogenic potential of the suspensor during early embryogenesis and inhibits premature germination (Lotan *et al.*, 1998). Ectopic expression of AtLEC1 in *Arabidopsis* resulted in the spontaneous formation of somatic embryos from mature tissues (Lotan *et al.*, 1998). A *LEC1* gene was isolated from Douglas fir (*PmLEC1*, *P. menziesii* *LEAFY COTYLEDON1*) using reverse transcription polymerase chain reaction (RT-PCR) and rapid amplification of complementary DNA ends PCR (RACE-PCR), and Northern analyses indicate that its expression is embryo

Table 1 Stage-specific genes isolated from Douglas fir

Gene	Function ^(a)	Expression ^(a)	Promoter	Application to biotechnology	Reference
<i>PmLEC1</i>	Initiates embryo morphogenesis, prevents precocious germination	EE ^(b) ME ^(c)	Yes	Potential to induce somatic embryogenesis from rare or mature tissues, marker of early embryogenesis	Vetrici and Misra, 2005

^(c)Peak of expression

specific, with transcript levels being highest during early embryogenesis (Vetrici and Misra, 2005). *PmLEC1* was cloned under control of the high-level CaMV 35S-35S-AMV (alfalfa mosaic virus) promoter and the NOS terminator in the pBI221 vector (Vetrici and Misra, 2005). *PmLEC1* rescued the *Arabidopsis lecl-1* null mutant and work is in progress to assess the spontaneous formation of somatic embryos (Vetrici and Misra, unpublished data). Transient expression of *PmLEC1* just to the point that somatic embryogenesis is induced from mature or rare tissues will save significant amounts of time because elite genotypes could be cloned directly and the field-testing phase would be eliminated. This will also serve to increase biodiversity.

Several other tissue-specific and developmentally regulated genes have been identified in Douglas fir (Table 1). The majority of these genes were isolated from differential screening or immunoscreening of stage-specific cDNA (complementary DNA) libraries. The corresponding regulatory sequences of these genes provide a repertoire of promoters for regulated transgene expression in Douglas fir and other conifers.

1. INTRODUCTION

1.1 History, Origin, and Distribution

In the late 18th century, French botanist Andre Michaux called the American elm (*Ulmus americana* L.) “nature’s noblest vegetable”. Many landscapers and homeowners felt the same way, and by the early 20th century, American elm trees were so popular that they were planted almost exclusively along streets in many US cities. Their tolerance of drought, pollution, and compacted soil made them ideal landscape trees, and they were a significant part of forest ecosystems as well. People admired their graceful form, whether rows of American elms were arching over a city street or a single huge tree was spreading majestically in a rural field (Figure 1). The popularity of elm trees is evidenced by the fact that “Elm Street” is one of the most generic and ubiquitous street name in the United States; it is even used in the media to refer to any residential street in any town in America. At the end of the 20th century, however, a few scattered individuals were all that remained of this once-dominant species.

Dutch-elm disease (DED) was first introduced to Europe about 1915 and the United States in 1930 (May, 1930; Heybroek *et al.*, 1982). It has since swept through each continent twice in separate pandemics (Brasier, 1991), killing most

mature trees within one or two growing seasons. DED is a vascular wilt disease caused by the introduced fungus *Ophiostoma ulmi* (Buisman) Nannf. or *Ophiostoma novo-ulmi* Brasier (hereafter referred to only as *O. novo-ulmi*, the cause of the more recent pandemics). Spores or hyphae of *O. novo-ulmi* can travel directly through root grafts of adjacent trees, but more commonly the disease cycle is completed through an insect vector that also spreads spores between trees. Elm bark beetles (either native North American *Hylurgopinus rufipes* or the European *Scolytus multistriatus*) feed on twig crotches of healthy adult elm trees, and then lay eggs under the bark of dying or dead elm trees, where *O. novo-ulmi* grows (Anderson and Holliday, 2003). After the eggs hatch, the larvae mature, and the adult beetles leave the dead tree, they carry *O. novo-ulmi* spores to healthy trees and complete the cycle. When *O. novo-ulmi* spores are deposited in the xylem vessels of a healthy, susceptible elm tree, they can spread passively through the plant’s vascular system. After spores germinate, hyphae can grow actively through pit membranes and infect other vessels (Hubbes, 1999). One of the plant’s responses to this invasion is to form bubblelike structures called tyloses, which typically swell and block the vessels in order to contain a pathogen. However, in the case of DED, the fungus generally spreads through and between vessels faster than the tyloses can

Figure 1 American elm in Poland, NY showing characteristic graceful vase shape [Photo courtesy of Fred N. Lampert]

contain it, so they only serve to intensify the wilting response.

Vessel size (both length and diameter) has also been correlated with DED resistance in some elm species. First, elm trees are most susceptible to DED in the spring, when their vessels are largest and transporting the most water (Hubbes, 1999). Smaller vessels would also be blocked more quickly by tyloses, which would increase the chances of effectively blocking the spread of *O. novo-ulmi*. Several experiments have reinforced these hypotheses. DED-resistant *Ulmus pumila* trees were shown to have lower conductivity and shorter or narrower vessels than susceptible *U. americana* trees (Elgersma, 1970). Vessel diameter and proportion of large vessels were correlated with susceptibility in *Ulmus minor* clones by Solla and Gil (2002), who concluded that resistance is proportional to speed of vessel compartmentalization. More recently, however, the same research group (Solla *et al.*, 2005) added that vessel size is not the only factor responsible for DED resistance, since the DED-tolerant *U. pumila* typically has larger vessels than the more susceptible *U. minor*.

Another significant response by the DED host is the production of phytoalexins called mansonones, which are produced in response to

elicitor molecules on the cell walls of the fungus (Yang *et al.*, 1989). Mansonones have been found in greater concentrations in DED-resistant than in susceptible elm species (Sticklen *et al.*, 1991), and in susceptible species when inoculated with less-aggressive forms of *O. ulmi* (Duchesne *et al.*, 1985), which indicates that they are probably a significant disease response in susceptible trees. When isolated from infected trees, mansonones have also been shown to inhibit the growth of *O. ulmi in vitro* (Sticklen *et al.*, 1991).

1.2 Botanical Description

Elms (*Ulmus* spp.) are in the strongly monophyletic family Ulmaceae, which together with Rosaceae, Cannabaceae, Urticaceae, Moraceae, and three or more other families, make up order Rosales (Sytsma *et al.*, 2002). The genus *Ulmus* consists of between 30 (Conde *et al.*, 2004) and 45 (Wiegrefe *et al.*, 1993) species, all of which are native to the northern hemisphere. Of these, a few are especially popular as plantation species. The English elm (*Ulmus procera*) has been planted in Great Britain for thousands of years. *U. procera* is almost entirely derived from a single clone that was introduced to England from Rome around 2000 years ago to be used for grapevine supports (Gil *et al.*, 2004). In The Netherlands, *Ulmus hollandica* (primarily clone “Belgica”) was planted extensively for landscaping, especially along the coast where they served as effective windbreaks and were very tolerant of salt spray (Karnosky, 1979). Both of these species are highly susceptible to DED, and any potential natural resistance from genetic diversity is reduced due to the fact that they are clonal.

In North America, the American elm (*U. americana* L.) was originally found throughout the eastern United States and southeastern Canada, and has since been planted throughout temperate areas of the continent due to its pleasing landscape characteristics and environmental tolerances. It can grow to be more than 500 years old and 42 m tall, typically with a spreading vase shape and a broad crown that can be wider than it is tall (Line, 1997).

Outside of intentional cultivation, the American elm is most commonly found in moist bottomland areas or near streams; mixed with ash, maple,

sugarberry, or sycamore in temperate hardwood forests (Bey, 1990). American elms, where they remain, are an important part of forest ecosystems, providing shelter and food for a variety of organisms. Squirrels, mice, birds, and deer eat the flowers and seeds, while bats and other small animals take shelter in the deeply grooved bark. American elm leaves contribute significantly to nutrient cycling and can improve soils, as they are high in calcium and other nutrients. In addition, they decompose relatively quickly compared to leaves from oaks, maples, and other common forest trees (Bey, 1990).

1.3 Economic Importance

People have cultivated elm trees (*Ulmus* spp.) for thousands of years. Long before they became popular for landscaping, elms were grown for grapevine supports in Italy and Spain, and their leaves were used for cattle feed when forage crops were insufficient (Karnosky and Mickler, 1986). Elm wood was historically used for timber, bows, wagon wheel hubs, and water pipes, and the bark was used by Native Americans for making rope and covering canoes (Smalley and Guries, 1993; Line, 1997). During World War II, elms' wide canopies and thick foliage were especially desirable for concealing factories and fortifications (Smucker, 1944). Elms are still grown for use as windbreaks, harvested for lumber, and of course planted for landscaping. The unique interlocking grain makes elm lumber resistant to splitting, and therefore ideal for bent or curved wood products, such as furniture, veneer, boats, and hockey sticks (Bey, 1990; Corchete *et al.*, 1997).

A street lined with mature American elm trees has an intrinsic aesthetic value that is difficult to quantify compared to timber or other commodity products. Left untreated, nearly all American elm trees that are exposed to DED will die within a few weeks to a few years, while trees grown to replace them take many decades to mature. In urban landscaping situations, this not only reduces aesthetic beauty and property value, but incurs significant additional expenses when dead trees have to be removed and disposed of (Cannon Jr and Worley, 1980). Therefore, treatment and prevention of DED are economically, aesthetically, and ecologically important.

1.4 Traditional Breeding and Treatment Options

Dr. Christine Buismann of The Netherlands, one of the first researchers to study DED in the early 20th century, also started a search for disease-resistant elms through selection and breeding programs (Holmes and Heybrook, 1990). One of the cultivars produced by this program, *U. hollandica* cv. "Commelin" is considered moderately resistant and is still being planted (Karnosky, 1979; Ben Jouira *et al.*, 1998). This program, along with various other selection, breeding, and testing programs, are still being maintained today.

Large-scale plantings for selection and breeding in the United States were started soon after the disease reached this continent. The United States Department of Agriculture (USDA) started a screening program in New Jersey in 1937, and had screened over 35 000 trees by 1944, at which point only one tree had lived through three successive inoculations with *O. ulmi* (Smucker, 1944). This program was interrupted by World War II, but restarted in 1970 in Ohio, and moved to Maryland in 1984, where it is still active today (Townsend and Douglass, 2001). Several commercially available DED-tolerant elm cultivars are products of this program, including "Valley Forge", "New Harmony", and some new cultivars that have not yet been released for general use, but show promise in screening experiments (Townsend *et al.*, 2005). Large-scale screening programs were also started at Cornell University in 1933 and the University of Wisconsin in 1958. The Wisconsin program incorporated breeding in 1969, and is also still active (Smalley and Guries, 1993). The popular "Liberty Elm" (actually a collection of six *U. americana* clones) is a product of the Wisconsin program, as well as "Independence", "Sapporo Autumn Gold", and several other cultivars that have been released for use by the nursery industry or the general public (see Sanatmour and Bentz, 1995, for a more thorough list of elm cultivars, common names, and hybrid histories). Despite its popularity, the Liberty Elm showed limited resistance to DED in more recent inoculation tests (Townsend and Douglass, 2001). Also, no DED-tolerant American elm clone has been reported to have resistance to elm yellows, a separate elm disease caused

by phytoplasma infections of phloem vessels (see Section 3.2). Of six Eurasian cultivars tested for elm yellows susceptibility by grafting infected bark patches, only one hybrid (cv. "Homestead") showed potential elm yellows resistance (Sinclair *et al.*, 2000). Between the programs mentioned above and other smaller breeding and selection programs, hundreds of thousands of American elm trees have been planted, grown, inoculated with *O. ulmi* and *novo-ulmi*, and observed for disease resistance.

Elms present unique difficulties to breeders as the popular species (American *U. americana*, English *U. procera*, and most clones of Dutch *U. hollandica*) are very susceptible to DED, but disease-resistant Asian species do not have the shape, growth characteristics, or environmental tolerances that make western species popular (Karnosky and Mickler, 1986). American elms are especially difficult to breed because they are tetraploid ($2n = 56$), instead of diploid ($2n = 28$) like other elms. Despite this restriction, early breeding programs (and later tissue culture experiments) tried for many years to hybridize American and Siberian elm (Redenbaugh *et al.*, 1981; Karnosky and Mickler, 1986). Of more than 20 000 controlled crosses performed between these two species, only about 100 seeds were obtained, and only a few of those germinated (Smucker, 1944). Even the most promising of these crosses did not have the leaf size or growth characteristics of full American elm.

At least one individual triploid elm was reported (purportedly with one American and one Asian parent, and many distinct American elm characteristics), and cuttings from this "hybrid" were shown to leaf out earlier, have intermediate leaf shape and size, and be disease resistant when compared to full American elms also grown from cuttings (Sherald *et al.*, 1994). This individual is a unique and valuable part of the American elm planting on the National Mall in Washington DC. This cultivar was initially designated NPS 3-487 and later named the "Jefferson Elm" (Sanatmour and Bentz, 1995). However, further tests revealed that NPS 3-487 is indeed a tetraploid full-American elm, albeit one with unusually high inherent resistance to DED (Townsend *et al.*, 2005).

Landowners and landscapers have tried a variety of preventative measures and treatments of DED. Given the fact that DED is spread by

beetles that breed in dead elm wood, the easiest and most effective DED control method is to remove and destroy (chip or burn) all dead elm wood. Sanitation programs are not 100 percent effective alone, but they are an essential part of all other DED prevention and control programs (Haugen and Stennes, 1999). One seemingly obvious preventative DED treatment involves using an insecticide to control the beetle vector. Spraying insecticides such as DDT has been performed with fair success in the past (Heybroek *et al.*, 1982), but the use of DDT was discontinued due to environmental concerns. Other insecticides have been used, but if the insecticide is applied by spraying, the entire crown of each tree must be treated, and multiple applications each season are usually necessary, which makes the process expensive and laborious, and likely to affect nontarget organisms. Beetle traps baited with pheromones have been widely used and can successfully attract large numbers of beetles (millions per year across the United States), but the ratio of beetles caught compared to the total population is still very small (Heybroek *et al.*, 1982).

A different strategy for controlling and preventing DED involves injecting fungicide or biological control agents directly into trees to kill or suppress *O. novo-ulmi*. Of course treatments of this type can only be applied to one tree at a time, making them expensive and impractical for widespread use outside of valuable landscape trees. Systemic fungicides can be effective in suppressing the fungus and all symptoms during the year of injection (Lanier, 1988), but they must be applied yearly for continued effectiveness, and if newly infected portions are not pruned out or retreated, symptoms from a single *O. novo-ulmi* inoculation can recur up to 4 years later (Campana, 1977; Sherald and Gregory, 1980). Various microbes have been tested *in vivo* for control of DED fungi and beetle vectors since the early 1980s, including *Trichoderma viride* (Ricard, 1983), *Pseudomonas syringae* (Myers and Strobel, 1983), *Streptomyces* spp. (O'Brien *et al.*, 1984), and *Phaeothea dimorphospora* (Bernier *et al.*, 1996). Some of these tests showed that the biological control agent induced resistance in the host when used preventatively, but none worked consistently as treatments against aggressive strains of DED. *Verticillium dahliae* was tested more recently as a preventative treatment against DED, and isolate

Vd-48 was found to significantly reduce wilting symptoms when inoculated 15–30 days before *O. novo-ulmi* inoculations, but *V. dahliae* could not be isolated outside the inoculation site as would be expected if it were systemic, and at high concentrations, it can cause its own disease symptoms (Solla and Gil, 2003).

Biological control of the disease vector has also been explored. *Bacillus thuringiensis*, which is commonly used to protect food crops from insect damage, as well as two *Trichoderma* species and *Scytalidium lignicola*, were shown by Jassim *et al.* (1990a, b) to increase mortality of both species of elm bark beetle when cultured on artificial media. Other *Bacillus* species tested in the same experiments gave mixed results, and no *in vivo* tests or techniques were published.

Nonaggressive strains of *O. ulmi* have been tested as preventative inoculations, and some caused increased host resistance to concurrent or subsequent inoculations with more aggressive strains (Scheffer *et al.*, 1980; Hubbes and Jeng, 1981). Increased DED resistance after exposure to less aggressive pathogens or other microbes may be partly due to physical blocking of vessels or lignin deposition, but is more likely due to an elicitorlike induction of plant disease responses (Solla and Gil, 2003) including mansonones as described below.

Other natural *O. novo-ulmi* control possibilities have been found in natural populations of the fungus. These viruslike agents, called d-factors, have been shown to reduce production of the *O. novo-ulmi* toxin cerato-ulmin (Sutherland and Brasier, 1995), and to reduce infections *in vivo* on both the susceptible *U. procera* and the more DED-tolerant *U. hollandica* “cv. Commelin” (Sutherland and Brasier, 1997). However, widespread success of d-factors as biological controls is unlikely because they would not spread between sexually or vegetatively incompatible populations of *O. novo-ulmi* (Hubbes, 1999), and would not spread at all if they did not increase the fitness of the organism.

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

Historically, the only way to genetically modify a plant to eliminate disease susceptibility or add new characteristics was through breeding and selecting desirable traits. Nearly all modern food crops

have been extensively modified through selective breeding, often to the point where they do not even resemble their wild progenitors. However, breeding is a lengthy process, especially in the case of slow-maturing trees, and it is impossible to determine ahead of time which parental traits will be passed on and expressed in progeny.

Genetic engineering, on the other hand, theoretically allows researchers to start with almost any plant source they choose, and add only one or a few genes that are necessary for resistance to a particular disease. The use of regulated promoters can refine the process even further, by directing where, when, and how much a given gene is expressed in the plant. Thus the process of producing a disease-resistant tree can potentially be faster, more controllable, and more predictable than traditional breeding (Giri *et al.*, 2004). Furthermore, in contrast to traditional breeding, parental explant sources for transgenesis can be selected for specific phenotypes, which would be far more likely to be maintained in all progeny. It is also easier to maintain genetic diversity in transgenic plants than traditionally bred selections by transforming a number of diverse genotypes. Genetic diversity is important for any plant population or restoration project, and has been specifically recommended for new elm releases (Karnosky, 1979). As global transport and the resulting inevitable spread of phytopathogens continues to accelerate, production of disease-resistant plants will become more urgent. Genetic engineering has the unique potential to accomplish this relatively quickly and effectively (Adams *et al.*, 2002).

A variety of methods have been employed to treat infected elm trees and prevent the spread of the disease, but many of these have been either ineffective, expensive, time-consuming, or detrimental to the environment (see descriptions of insecticides and fungicides in Section 1.4). Selection programs to find and breed American elm trees with natural DED resistance have had some success in producing DED-tolerant American elms, but the growth and selection process is very slow and not controllable. Also, any attempts to “breed in” resistance to American elm from other elm species are difficult due to ploidy differences between American and all other elms, and may result in trees without the desirable aesthetic characteristics of classic American elms. Finally, if trees are selected or bred only for DED

resistance, it is likely they would be susceptible to other known elm pathogens such as elm yellows, and they would not have the genetic diversity necessary to tolerate new diseases or environmental pressures.

Transformation of American elm trees with genes for DED resistance, under the control of regulated promoters, has the potential to produce trees that are truly resistant to DED. These resistant transgenic trees can be from a variety of genetic backgrounds, and have all the popular growth characteristics of American elms. Preliminary evidence as presented in this study suggests that genes encoding small antimicrobial peptides in particular show great promise for DED resistance, since they are naturally active against

microbes but harmless to plants and animals, and they can be synthesized to enhance these or other characteristics. Promoters that express these genes specifically in the vascular tissue, or only in response to fungal invasion, could mitigate concerns of reduced growth effects or interference with mutualistic soil microbes.

2. DEVELOPMENT OF TRANSGENIC ELM

2.1 Donor Gene

The plasmid construct initially used to transform American elms in this project was designated pSE39 (Figure 2). Starting at the right border

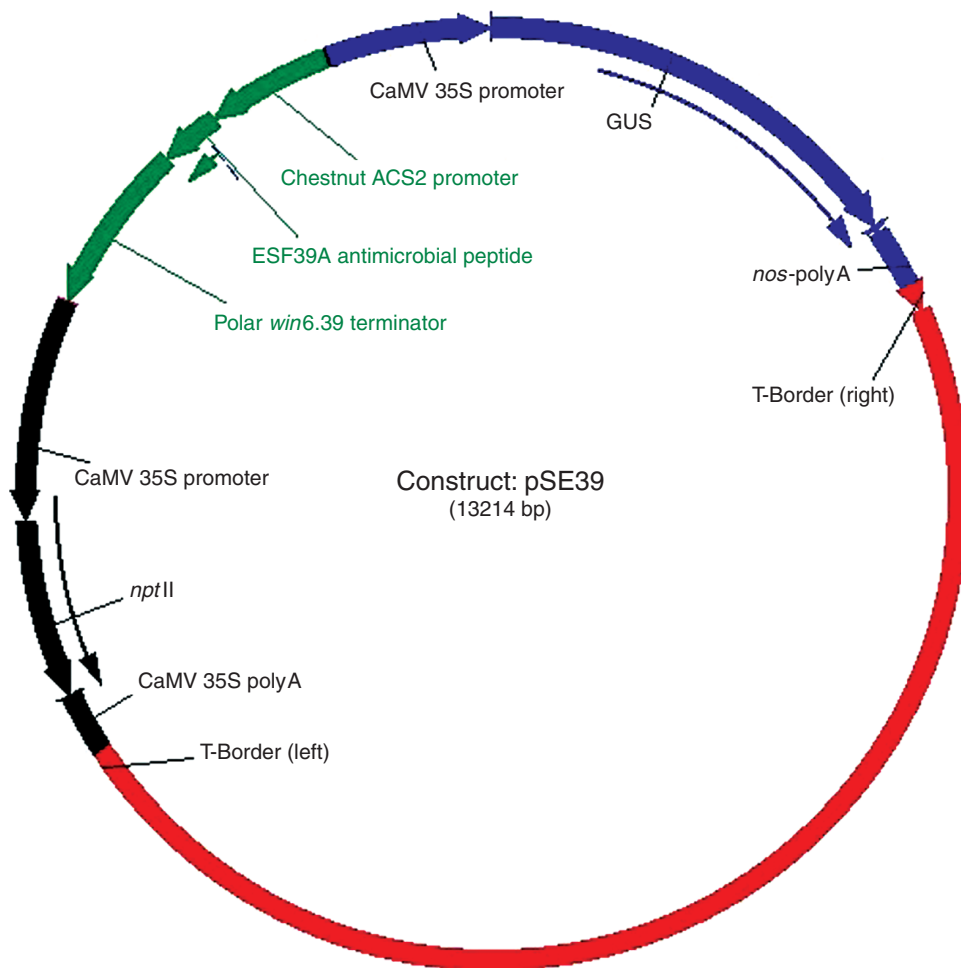

Figure 2 Plasmid pSE39 showing the GUS marker gene, the ESF39A antimicrobial peptide, and the *nptII* selectable marker

of the transfer-DNA (T-DNA), the first gene in this construct is *uidA* (codes for GUS, or β -glucuronidase). The constitutive cauliflower mosaic virus (CaMV) 35S promoter regulates this gene's expression, so all tissues in a transformed plant should express the GUS marker gene. It is followed by a nopaline synthase (*nos*-polyA) terminator.

The second gene, *ESF39a*, encodes a 39-amino acid protein that will be processed by the cell into antimicrobial peptide ESF22B, along with an N1a protease recognition sequence (Powell *et al.*, 2000). This protein has a unique amino acid sequence, but was designed to have the same α -helical, amphipathic structure as magainin-type antimicrobial peptides (Zasloff, 1987, see below), with enhanced antifungal and reduced hemolytic activities (Powell *et al.*, 1995, 2000). Proteinase recognition sites were also included to facilitate breakdown in vertebrate digestive systems. This gene is controlled by the *ACS2* promoter, which was cloned from American chestnut (*Castanea dentata*) and has been shown to express specifically in vascular tissue (Connors *et al.*, 2002). It is followed by the terminator from the wound-inducible chitinase gene, *win6.39*, originally isolated from poplar (Clarke *et al.*, 1994).

The third and final gene in pSE39 is the selectable marker *nptII* (neomycin phosphotransferase II), driven by a separate, oppositely oriented CaMV 35S promoter, for resistance to neomycin-class antibiotics including kanamycin. It is followed by a CaMV 35S polyA terminator. This allows early selection of potentially transformed shoots, as nontransformed tissue culture shoots should not survive on media with kanamycin. The selectable marker was intentionally placed farthest from the right border, to prevent survival of partially transformed shoots if the T-DNA failed to insert completely.

Cationic antimicrobial peptides are short, amphipathic proteins that inhibit growth of a variety of microbes. Epithelial surfaces, blood, and mucosal secretions from humans have been known to have bactericidal properties for almost a century (Skarnes and Watson, 1957; Ganz and Lehrer, 1999; Brogden, 2005). Some of these early researchers correctly inferred that the factors responsible for these properties were specifically active against negatively charged membranes, and were inducible by microbes. By the mid-

20th century, antimicrobial peptides (AMPs) were studied and described in more detail after being extracted from phagocytotic granules (Hirsch, 1956). At this point, they were known to be proteins that increased permeability of microbial membranes. More detail was elucidated with the discovery and characterization of cecropin class AMPs from *Cecropia* moth pupae, after the realization that insects showed an immune response without the lymphocytes or immunoglobulins that characterize vertebrate immune systems (Steiner *et al.*, 1981).

A different class of AMPs was discovered after the observation that *Xenopus* (African clawed frogs) rarely contracted microbial diseases, even when lesions and contaminated environments provided ideal conditions for infection (Chen *et al.*, 1988). Researchers studied *Xenopus* skin and isolated some of these AMPs, designated magainins, which were found to be effective against bacteria, fungi, and protozoa, but again not harmful to higher eukaryotes (Zasloff, 1987).

Over 880 AMP sequences have been published as of 2005 (Brogden, 2005), and thousands more probably exist. Various types of AMPs are found in a wide variety of organisms, including bacteria (Kristiansen *et al.*, 2005), fungi (Reddy *et al.*, 2004), most plants and all plant organs (Broekaert *et al.*, 1997; Fujimura *et al.*, 2005), many invertebrates (Richman *et al.*, 1997; Lamberty *et al.*, 2001), and a variety of vertebrates (Hancock and Scott, 2000; DeGray *et al.*, 2001). Their broad activity and relatively rapid response make AMPs ideal pathogen-fighting agents where a complex or adaptive immune response is absent or reduced. For example, most insects' response to pathogens that penetrate the cuticle is primarily mediated by AMPs (Lamberty *et al.*, 2001). Increased expression of AMPs has been shown in human newborn skin before more advanced immune defenses develop (Dorschner *et al.*, 2003). Also, high levels of AMP expression have been shown in plant germination both before and immediately after the seed coat breaks, at a time when other plant defenses are not fully functional (Terras *et al.*, 1993, 1995; Broekaert *et al.*, 1997).

AMPs are also being tested as treatments for a variety of human maladies, including cystic fibrosis-related lung infections and associated swelling (Zhang *et al.*, 2005), some types of cancer (Jacob and Zasloff, 1994; Doyle *et al.*, 2003), and

sexually transmitted diseases (STDs) including HIV and Herpes simplex virus (Yedery and Reddy, 2005). More diverse uses include disinfecting drinking water (Suarez *et al.*, 2002), use as a spermicidal contraceptive (Reddy *et al.*, 2004), and immobilizing *E. coli* on microtiter plates for detection (Gregory and Mello, 2005).

The modes of action of AMPs are diverse and not completely understood, but most rely on the amphipathic structure and attraction of cationic peptides to anionic microbial membranes (Epand and Vogel, 1999). Most AMPs are positively charged, and this charge is attracted to negatively charged lipids on prokaryotic cell membranes (Chen *et al.*, 2001), but not to cholesterol-containing membranes in advanced eukaryotic cells (Maloy and Kari, 1995; Tytler *et al.*, 1995). Various specific mechanisms have been proposed (Brogden, 2005), which generally show AMPs binding to prokaryotic membranes and disrupting ion transport and membrane permeability, which leads to cell death (Matsuzaki *et al.*, 1997; Ibrahim *et al.*, 2000). AMPs have also been shown to inhibit nucleic acid or protein synthesis (Brogden, 2005), to degrade mitochondria in fungi (Kristyanne *et al.*, 1997), and to change hyphal morphology or interfere with cell wall formation in fungi (Rajasekaran *et al.*, 2001).

Activity of AMPs against plant pathogens has been well documented both *in vitro* and *in vivo*. Cecropins, magainins, and synthetic magaininlike peptides have previously been shown to inhibit several bacterial and fungal plant pathogens *in vitro*, including *O. ulmi* (Jacobi *et al.*, 2000; Alan and Earle, 2002). Rice blight (*Rhizoctonia solani*) was strongly inhibited by cecropins and synthetic peptides (Oard *et al.*, 2004). Several important fungal phytopathogens including *Cryphonectria parasitica*, *Fusarium oxysporum*, and *Septoria musiva* were inhibited by synthetic magainin-based peptides, while host plant pollen germination was not affected (Powell *et al.*, 1995, 2000). Other plant pathogens that have been shown to be inhibited by a synthetic AMP include *V. dahliae* and *Phytophthora parasitica* (Rajasekaran *et al.*, 2001).

The many benefits of AMPs, especially their very broad antipathogenic activity and ease of synthesis and modification, make their encoding nucleotide sequences ideal candidates for use as transgenes. Many plants and even some animals have been transformed with AMPs, and most of these

have shown increased resistance to a particular pathogen or disease. Tobacco (*Nicotiana*), a model plant that is relatively easy to transform and propagate, has been transformed with a variety of types of AMPs, and the resulting transgenic plants were shown to be resistant to a variety of pathogens. Cecropin analogs increased resistance of tobacco to *Pseudomonas* bacterial wilt (Jaynes *et al.*, 1993), synthetic peptide D4E1 increased resistance to fungal pathogens (Cary *et al.*, 2000), a modified magainin increased resistance to an oomycete and bacteria (Li *et al.*, 2001), synthetic magainin analog MSI-99 increased resistance to bacteria and fungi when expressed from either the nuclear or chloroplast genome (DeGray *et al.*, 2001; Chakrabarti *et al.*, 2003), and overexpressed natural AMPs isolated from *Pharbitis nil* plants increased resistance to fungi (Koo *et al.*, 2002). Other nonwoody plants that have shown resistance to fungal pathogens when transformed with genes encoding AMPs include geranium, which was resistant to *Botrytis* (fungal blight) when transformed with a natural AMP from onion (Bi *et al.*, 1999); banana, which was resistant to multiple fungal pathogens when transformed with MSI-99 (Chakrabarti *et al.*, 2003); and potato, which was resistant to *Phytophthora* in tissue culture when transformed with a Cecropin-melittin hybrid AMP (Osusky *et al.*, 2000). More recently, potato was transformed separately with two magainin-class AMPs, both of which provided broad-spectrum blight and rot resistance and significantly increased potato storage times (Osusky *et al.*, 2004; Osusky *et al.*, 2005).

In addition to agricultural plants, some tree species have been transformed with AMPs and have also shown increased resistance to phytopathogens. For example, hybrid poplar was transformed with two AMPs (synthetic ESF12 and an Ac-AMP1 analog), and leaf disks with each construct showed fewer necrotic spots than nontransgenic controls (Liang *et al.*, 2002). Another hybrid poplar transformation resulted in increased resistance to two bacterial pathogens (*Agrobacterium tumefaciens* and *Xanthomonas populi*), but no significant effect on a fungal pathogen (*Hypoxyylon mammatum*) (Mentag *et al.*, 2003). Mixed results were also obtained with transgenic pear and apple trees expressing AMPs for resistance to fire blight and scab, respectively (Reynold *et al.*, 1999; Faize *et al.*, 2004).

Another plasmid construct, currently being tested in American elm transformations, includes a defensin isolated from spruce (A. Seguin, personal communication). Plant defensins are a class of AMPs consisting of small, basic peptides found in more than 80 plant species (Broekaert *et al.*, 1997). Like other AMPs, they inhibit a broad range of fungi, yet are nontoxic to mammalian or plant cells. They are mainly expressed in the peripheral cell layer, which is consistent with a role in a first line of defense against pathogens (Thomma *et al.*, 2002). PgD1 (*Picea glauca* defensin 1), a defensin isolated from *P. glauca*, has exhibited strong antifungal activity *in vitro* (Pervieux *et al.*, 2004). PgD1 was reported to be up-regulated by wounding and jasmonic acid treatment, as well as during seed germination. This suggests it is important in both constitutive and induced defense responses. A recombinant protein expressed by PgD1 *in vivo* was shown to cause extensive growth inhibition of three

fungus pathogens (*Cylindrocladium floridanum*, *F. oxysporum*, and *Nectria galligena*) (Pervieux *et al.*, 2004). Therefore, PgD1 could potentially be used to inhibit growth of ascomycete pathogens including *O. novo-ulmi*. Other studies have shown that transgenic expression of plant defensins can protect vegetative tissues from pathogen attack as well. For example, constitutive expression of a radish defensin enhanced resistance to the fungal leaf pathogen *Alternaria longipes* (Terras *et al.*, 1995), and constitutive expression of an alfalfa defensin in potato provided resistance to *V. dahliae* under field conditions (Gao *et al.*, 2000). Research is currently underway to investigate constitutive and vascular expression of PgD1 in transgenic American elm. PgD1 will be expressed in the elm vascular system by the cinnamyl alcohol dehydrogenase promoter *EgCAD* from *Eucalyptus gunni* (Feuillet *et al.*, 1995), from plasmid pMJMegCADDEF as seen in Figure 3.

Figure 3 Plasmid pMJMegCADDEF [Source: A. Seguin, personal communication]

2.2 Methods Employed

American elm seed was purchased from F.W. Schmacher Co, Inc. (Sandwich, MA). American elm seedlings in pots and explants in tissue culture were grown on a light bench with a 16-h day, 8-h night cycle. For each transformation experiment, fully expanded young leaves were collected from seedlings, surface sterilized in 10% bleach for 10 min, rinsed, and sliced into approximately 1 cm² containing part of the midvein. Leaf pieces were co-cultivated with *A. tumefaciens* strain EHA105, containing the binary vector pSE39, in a minimal sucrose-based medium containing acetosyringone for *vir* gene induction (Gelvin and Habeck, 1990). After this liquid co-cultivation step, leaf pieces were placed on solid tissue culture media without selection for 3–5 days, rinsed with carbenicillin and cefotaxime, and then cultured on medium containing both of these antibiotics to ensure they were free of *Agrobacterium* (see Newhouse *et al.*, 2006 for a more detailed review of this transformation procedure and of tissue culture protocols and media).

2.3 Selection of Transformed Tissue

All putatively transformed shoots were regenerated under 100 µg ml⁻¹ kanamycin selection in tissue culture for at least 8–12 weeks (at least 3 transfers). When shoots were large enough to harvest a leaf tip (>9 mm²), they were screened with a GUS assay (see Section 2.1; Newhouse, 2005) to confirm the presence and expression of t-DNA in the plant genome. Each leaf tip was soaked in X-GLUC (5-bromo-4-chloro-3-indolyl β-D-glucuronide) overnight at 37 °C, and then soaked in 70% ethanol to remove chlorophyll from the tissue. Transformed tissue stained a dark blue color, while nontransformed tissue was colorless or light brown.

2.4 Regeneration of Whole Plants

Micropropagation or tissue culture of elm trees is essential for any genetic engineering program, and it would be beneficial for multiplying trees in traditional breeding or selection projects as well. At least two DED resistant European/Asian elm hybrids have been regenerated and multiplied in

tissue culture (Ben Jouira *et al.*, 1998; Mensuali-Sodi *et al.*, 1998). Furthermore, initial screenings for resistance to DED can be performed *in vitro*, which is easier and faster than inoculating trees in the field (Pijut *et al.*, 1990; Domir *et al.*, 1992; Krause *et al.*, 1996).

Elm trees were among the first woody plants to be successfully established in tissue culture (TC), from a cambial tissue explant of *Ulmus campestris* by R.J. Gautheret in 1940 (Karnosky and Mickler, 1986; Moore, 2003). Gautheret was not able to regenerate whole plants from his TC, however, and it was nearly 35 years before this was accomplished. *U. campestris* and *U. americana* were both successfully cultured and regenerated from stem section explants by two independent researchers around the same time (Chalupa, 1975; Durzan and Lopushanski, 1975). More recent elm TC efforts have focused on simplification and efficiency of the entire process. The use of leaf pieces as explants allows easier, less destructive explant collection, and more explants can be taken from each source plant. American elm leaf pieces were first used as explants in 1991 (Bolyard *et al.*, 1991b), and George and Tripepi (1994) studied American elm leaf explant TC conditions in more detail to improve regeneration efficiency.

Transformation of American elm for resistance to DED has been a goal almost as long as genetic engineering has been in existence (Sticklen *et al.*, 1991), but no report of *U. americana* transformation was published prior to the present study (Newhouse, 2005). The first elm to be transformed was the “Pioneer” hybrid (*Ulmus glabra* × *Ulmus carpinifolia*), for which internode stem sections were transformed separately with *Agrobacterium* and biolistics, each carrying the *GUS* gene (Bolyard *et al.*, 1991a). The hybrid elm “Commelin” ((*U. glabra* × *U. carpinifolia*) × *U. carpinifolia*) was cultured with an armed strain of *A. tumefaciens* and produced agropine-containing tumors, but no transgenesis with modified t-DNA was reported (Dorion *et al.*, 1995). English elm shoots have also been transformed with wild-type *Agrobacterium* (Fenning *et al.*, 1996), *Agrobacterium* carrying *GUS* and *nptII* genes (Gartland *et al.*, 2000), and more recently with *Agrobacterium* carrying a putative fungal resistance gene (Fenning *et al.*, 2005).

The TC protocol used in this experiment was originally inspired by an earlier publication showing regeneration of shoots from American

Figure 4 American elm shoot in tissue culture

elm leaf pieces (George and Tripepi, 1994), and is described in detail elsewhere (Newhouse, 2005; Newhouse *et al.*, 2006). Briefly, media consisted primarily of Driver and Kuniyuki Walnut medium (Driver and Kuniyuki, 1984) with 1X Nitsch and Nitsch vitamin powder (both from Phytotechnology Laboratories) supplemented with 22 μ M benzyl adenine (BA), 0.1 μ M indole-3 butyric acid (IBA), and 94 μ M AgNO_3 for shoot initiation; 5.5 μ M BA and 0.22 μ M IBA for shoot elongation; and 0.2% w/v activated charcoal for rooting. Leaves were placed face down (veins up) on Petri plates of shoot initiation medium until buds formed and just began to expand. Buds were transferred to MagentaTM cubes containing shoot elongation medium, where they multiplied and were subcultured every 3–4 weeks as new shoots formed (Figure 4). When shoots reached the top of the magenta cube or started to become woody, they were cut from the cluster of smaller shoots and callus, dipped in 1 mM naphthaleneacetic acid (NAA), and put in a tall MagentaTM cube of elongation medium. When roots became visible, the rooted shoot was carefully removed from the charcoal medium, potted in a peat-based potting mix, and slowly acclimated to ambient humidity.

2.5 Testing

2.5.1 Minimum inhibitory concentration (MIC) assay

The translated core of the ESF39A synthetic AMP (ESF22B) has been shown to inhibit growth

Figure 5 Pressure bomb apparatus

of multiple bacterial and fungal pathogens *in vitro*, and *S. musiva* specifically *in vivo* (Powell *et al.*, 2000; Liang *et al.*, 2002). However, the concentration at which this peptide inhibits growth of *O. novo-ulmi* had not previously been determined. Therefore, *O. novo-ulmi* was cultured with 0–100 μ M dilutions of ESF22B to determine the *in vitro* MIC. This procedure was based on the MIC assay by Catranis (1999).

ESF22B was suspended in sterile, distilled water, mixed with potato dextrose broth and low-melting point agarose, and diluted to a series of 12 concentrations ranging from 0 to 100 μ M in a 96-well culture plate. Approximately 100 *O. novo-ulmi* conidia (ATCC 34359) were added to each well. The plate was stored for 96 h in indirect light (16 h light, 8 h dark) at 23 °C. In five separate assays, 2.5–5.0 μ M ESF22B inhibited growth of *O. novo-ulmi*. However, when wild-type American elm sap was mixed with ESF22B and incubated at room temperature for 30 min prior to the assay, peptide concentrations of at least 42 μ M were required to inhibit *O. novo-ulmi*. A portable “pressure bomb” (PMS Instrument Company, Corvallis, Oregon) was used to extract total vascular sap from wild type and transgenic *U. americana* leaves (Figure 5). Two separate assays showed that the MIC of ESF22B, when exposed to wild-type American elm sap, was about 10 times greater than the MIC without sap (Newhouse *et al.*, 2007). Therefore, American elm sap or one of its constituents must have a moderately inhibitory effect on the activity of the ESF AMP. One possible cause

could be relatively high concentrations of cations such as Ca^{2+} in the elm sap. These cations could interfere with the specificity of AMPs to anionic membranes, which has been previously reported (Mills and Hammerschlag, 1993; Harrison *et al.*, 1997; Zhang *et al.*, 2005). This problem may be addressed by increasing expression levels of the peptide *in planta*, or by modifying the synthetic peptide so it is less sensitive to cations or other inhibitors in the sap.

2.5.2 Mycorrhizae

One question that should be raised when transforming plants to express antimicrobial compounds is whether beneficial microbes (i.e., mycorrhizal fungi) will be affected. Mycorrhizae are modified roots colonized with fungi in which, typically, the fungus supplies the plant with nutrients in exchange for energy in the form of photosynthate from the plant. Preliminary observations suggest that slower field growth of transgenic poplar constitutively expressing a wheat oxalate oxidase gene (Liang *et al.*, 2001) may be correlated with reduced mycorrhizal colonization (Horton and Powell, 2006). However, other research has shown that mycorrhizae may not abnormally affect or be affected by transgenic plants. For example, Turrini *et al.* (2004) concluded that aubergine (*Solanum melongena*) constitutively expressing a natural AMP isolated from *Dahlia* was resistant to pathogenic *Botrytis* and *Verticillium*, while symbioses with mycorrhizal *Glomus mosseae* were not significantly affected.

Mycorrhizae may have other effects on American elm pathogens as well, either directly or by contributing to the overall health of the plant. Several studies have explored possible relationships between mycorrhizal colonization and insect herbivores, which would be potentially applicable to the elm bark beetles that spread *O. novo-ulmi*. Conclusions of these studies varied widely, however, depending on the organisms studied and even on soil conditions (Borowicz, 1997; Rieske, 2001; Vicari *et al.*, 2002). Clearer results were seen when mycorrhizae were tested with some microbial pathogens. For example, mycorrhizal tomatoes infected with either fungal root pathogens or yellows-causing phytoplasmas showed less severe disease symptoms, and growth characteristics

more similar to healthy plants, when compared to nonmycorrhizal controls (Trotta *et al.*, 1996; Lingua *et al.*, 2002). This study is especially applicable to elm research, as the phytoplasma causing elm yellows is another significant threat to American elm trees (Sutherland *et al.*, 1997). Even if mycorrhizae do not have a direct effect on the DED pathogen or vector, healthy mycorrhizal relationships are important to consider when producing trees designed to have antimicrobial properties.

In order to quantify mycorrhizal colonization, roots were collected from healthy American elm trees with new growth approximately 3 months after field planting, from four wild-type seedlings and four transgenic plants. Staining was performed according to Brundrett *et al.* (1996). In brief, roots were rinsed over a 0.5 mm sieve and cleared by autoclaving at 121 °C for 15 min in 10% KOH (potassium hydroxide), fungal structures were stained by autoclaving again in Chlorazol Black E, and stained roots were stored in 50% glycerol at room temperature. Mycorrhizal colonization was quantified on 30 root samples from each plant using the “magnified intersections” technique (McGonigle *et al.*, 1990) with minor modifications. All individuals in both the transgenic and wild-type groups had formed extensive mycorrhizal associations within 3 months after field planting; differences in percent colonization between these groups were not significant ($p = 0.959$) in an unpaired *t*-test. Therefore, according to the data collected so far, mycorrhizal colonization of American elm trees is not affected by expression of the ESF39A AMP.

2.5.3 Molecular tests

DNA was extracted from wild type and transgenic elm leaf tissue using a modified hexadecyl trimethyl ammonium bromide (CTAB) procedure (Lodhi *et al.*, 1994). Polymerase chain reaction (PCR, Mullis and Faloona, 1987) with custom primers for the *ESF39a* and *GUS* genes confirmed T-DNA insertion into the elm genome (see Newhouse *et al.*, 2007 for more information on PCR primers and conditions). Southern hybridization was performed to distinguish between different transformation events (on buds originating from the same leaf piece) as well as to determine

transgene copy number. Genomic DNA was digested separately with two restriction enzymes, and a ^{32}P -labelled segment of the *GUS* gene was used as a probe. Single bands were produced in nine transgenic samples digested with two separate restriction enzymes. These nine individuals were determined to consist of multiple samples from only four transgenic events. Single bands provide evidence that each of these four lines contain only one copy of the T-DNA from the pSE39 construct. While it is unusual that all four tested events have only one copy of the t-DNA (Pappinen *et al.*, 2002; Polin *et al.*, 2006), *Agrobacterium* typically introduces fewer copies of transgenes than biolistics (Shou *et al.*, 2004), and there are several more elm transgenic lines that have not yet been tested for copy number.

2.5.4 Inoculation tests

Transgenic and nontransgenic trees were inoculated with *O. novo-ulmi* conidia to determine *in vivo* effectiveness of *ESF39a*. *O. novo-ulmi* (ATCC, 34359) was cultured on potato dextrose agar (PDA) for 1–3 weeks. Sterile water was washed over the fungal colony and diluted if necessary to a final concentration of about 1×10^8 conidia/ml. Trees at least two growing seasons old were inoculated with 20 μl of this spore solution, applied via a pipette into a vertical scalpel wound (Figure 6). Inoculated trees were kept in a growth chamber

Figure 6 Inoculation of young *U. americana* with *O. novo-ulmi*

or greenhouse at room temperature and observed for 11–15 weeks. Leaf color, presence of wilting, and any loss of leaves was observed. Wild-type seedlings were inoculated with sterile water to determine whether the inoculation procedure was harmful to the tree, and no staining or wilting was observed in these control trees.

After the inoculation observation period, inoculated trees were once again collected in the lab. Each tree was felled with a large scalpel or utility knife at least 2 cm below the inoculation point, leaving at least 2 cm of stump above the soil level. Each removed shoot was cut at an angle to observe any staining at the inoculation point and sectioned every 2 cm above and below the inoculation point. Sections of stained stem tissue were surface sterilized, cut into wedges, and placed on PDA media. *O. novo-ulmi* was successfully recultured from all stained tissue cultured in this manner, but not from unstained tissue or from noninoculated trees.

Some symptomatic differences were observed after an *O. novo-ulmi* inoculation experiment in which six nontransformed TC-derived trees were compared to six transgenic trees from each of two lines (designated FS5 and AN1). Eleven weeks after inoculation, nontransformed trees retained an average of 9% of their leaves, FS5 trees retained 41%, and AN1 trees retained 67%. These numbers decreased to 7%, 18%, and 52%, respectively, after 13 weeks, and were proportionally similar after 14 weeks. Despite the consistent trends, none of these differences in leaf retention between clones were statistically significant ($p > 0.05$).

Staining was present to some extent in all trees from this inoculation experiment, but the maximum distance at which the staining was observed below the inoculation point (Scala *et al.*, 1997) varied significantly 14 weeks after inoculation (Newhouse *et al.*, 2007). ANOVA and Tukey's Honestly Significantly Different (HSD) test revealed that in AN1 trees, staining spread a significantly shorter distance below the inoculation point than in nontransgenic control trees ($p < 0.05$), but spread of staining in FS5 trees was not significantly different from the other groups. Additionally, stem tissue above the inoculation point was dried and dead in four of the six nontransgenic controls and four of the six FS5 trees, but the entire stem was alive in all six AN1 trees.

Inoculation results from this project should be considered preliminary, since young elm trees are not as susceptible to DED as are mature trees (Townsend *et al.*, 1995; Gartland *et al.*, 2000). Furthermore, susceptibility can vary according to season and environmental conditions (Sutherland *et al.*, 1997; Hubbes, 1999), and the greenhouse conditions used in this study may not represent true field conditions. Expanded field inoculation tests are currently being planned.

2.6 Specific Regulatory Measures Adopted

The ESF39A AMP was designed specifically to be harmless to humans and animals, and since it is only expressed in the vascular system, the authors do not believe it poses any special risks. At the time of writing, the SUNY College of Environmental Science and Forestry has a 5-year USDA permit for temporary controlled field-testing of transgenic elm trees (see Section 3.2). Long-term permissions and other permits are pending.

3. FUTURE ROAD MAP

3.1 Expected Products

Most genotypes of American elm are relatively easy to propagate via softwood cuttings (Doran and McKenzie, 1949; Hartmann and Kester, 1983). This will facilitate the large-scale production of planting stocks of resistant clones that could be released as patented named varieties. The transformation events described in this chapter will be evaluated in field tests along with “Liberty”, “New Harmony”, “Valley Forge”, and possibly other reportedly DED-resistant American elm varieties. If the ESF39A AMP does confer DED resistance at least as strong as the other resistant American elm varieties, the authors plan to, at a minimum, patent, clonally propagate, and release the most resistant transformation event as a new variety. The authors would prefer to transform, test, and release several additional clonal varieties, each derived from a different genetic background and transformation event. However, all these goals depend on the availability of funding, the level of resistance provided by the ESF39A peptide, and the cost and effort required to successfully obtain a

“Determination of Nonregulated Status” from the United States Department of Agriculture Animal and Plant Health Inspection Services Biotechnology Regulatory Service (USDA-APHIS BRS).

3.2 Addressing Risks and Concerns

The transgene products described in this study were designed specifically to be harmless to plants and animals, and since they are not expressed in pollen, and humans do not consume elm products, potential allergic reactions should not be a concern. The transgenic trees will be field-tested under permits from the USDA-APHIS BRS. Once transgenic lines are identified that demonstrate substantial pathogen resistance and are substantially equivalent to nontransgenic clones, applications for deregulation will be submitted to the two US agencies that have regulatory oversight over the release of transgenic plants: USDA-APHIS BRS and the Environmental Protection Agency (EPA). Since the elms do not produce a food crop, they do not need to be reviewed by the Food and Drug Administration (FDA). To ensure transparency of the research and raise public awareness, educational outreach plots mirroring the larger field trials have been planted (Figure 7).

Ideally, genes for American elm disease resistance could be isolated from DED-resistant species within *Ulmus*, and employed as transgenes controlled by wound-induced or vascular-specific promoters from other closely related species (Hollick and Gordon, 1993; Connors, 2001). It could also be beneficial to study relative gene expression levels in American elm trees that show unusually high levels of tolerance to DED, such as the Jefferson Elm that was originally thought to be an American–Asian hybrid. A gene encoding a chitinase-like protein has been isolated from this elm clone, and was found to be effective in reducing brown patch disease when expressed in creeping bentgrass (Chai *et al.*, 2002). It is possible that simply changing the expression pattern of an existing elm gene through the use of a different promoter could provide increased levels of resistance not found in most American elms. These existing genes could include chitinases, as well as those that control tylose formation, vessel diameter, or mansonone production. Other potential sources for transgene products could

Figure 7 Public educational outreach plot featuring transgenic American elm

be based on existing DED control mechanisms, including a gene product based on d-factors (the naturally occurring viruslike particles in some *O. novo-ulmi* populations). These would make use of DED devices that have already evolved specifically with this pathogen, and would likely reduce public concern associated with donor genes from distantly related organisms.

The transgenic American elms resulting from transformations with naturally occurring, DED-related genes or promoters would be resistant to *O. novo-ulmi* specifically, and effects on nontarget organisms would theoretically be almost nonexistent. However, microarray or other gene expression analysis and isolating disease resistance genes can be complicated and time-consuming processes. Therefore, the most efficient alternative for the time being is to use known genes with the highest fungal resistance and fewest unintended effects possible. AMPs, as described in this publication, clearly have great potential for control of DED.

One important consideration for any DED research program is susceptibility to elm yellows. The causative organism of this disease, variably called a phytoplasma (Lingua *et al.*, 2002) or a mycoplasma-like organism (Zhao *et al.*, 2004), is part of a weakly defined group of microorganisms that cause yellows diseases by infecting phloem tissue in a variety of plant groups. They are usually spread by hoppers or other sucking insects, and cannot be cultured *in vitro*, so inoculation experiments rely on propagation of infected insect vectors or grafting of infected plant tissue. Symptoms of elm yellows, as the name suggests, start with yellowing of leaves and usually result in death within a few seasons of infection (Sinclair, 2000). Identification of infected trees before symptoms are visible (or if symptoms may be confused with those of DED) can be accomplished by PCR with phytoplasma-specific primers (Lee *et al.*, 1993). One potential way to address elm yellows is to transform elms with

phloem-specific promoters (Zhao *et al.*, 2004), which could be used to control expression of AMPs or other gene products. The vascular-specific promoter (*ACS2*) used in the current project should be tested to determine whether it is active in both phloem and xylem vessels, which has been reported for homologous gene promoters in other plant systems (Zhang *et al.*, 2000).

It is of course possible that pathogens could develop resistance to almost any transgene product. However, assuring the continued presence of wild-type susceptible individuals, avoiding large plantings of a single clonal transformant, and transforming plants with multiple genes (Dixon, 2001) are all effective strategies for reducing pathogen-acquired resistance. *Agrobacterium*-mediated transformation with multiple constructs (Li *et al.*, 2003) is one method of “pyramiding” resistance genes, or a single construct can be modified to express multiple protein products in different tissues (Francois *et al.*, 2002).

3.3 Expected Technologies

The current research suggests that higher pSE39 expression levels could be more effective against *O. novo-ulmi*. This may necessitate the use of a different promoter, or it could be as simple as testing or creating more transformed lines, since expression can vary greatly between multiple lines transformed with the same construct (Peach and Velten, 1991). In addition to the AMPs described above, transgenes that hold particular promise for phytopathogen resistance in trees include chitinases (Pappinen *et al.*, 2002; Pasonen *et al.*, 2004), oxalate oxidases (Liang *et al.*, 2001; Polin *et al.*, 2006), and RNA interference (Escobar *et al.*, 2002) (see Powell *et al.*, 2006 for a more thorough review of tree transgenesis research progress to date). Oxalate oxidase (OxO) may be especially appropriate for transgenic tree restoration work (Grover and Gowthaman, 2003; Powell *et al.*, 2006). This enzyme converts oxalic acid to H₂O₂, which can have direct antifungal properties and reduce fungal pathogenicity, as well as serving as a defense response signal to stimulate natural plant defenses (Stuiver and Custers, 2001). Oxalate oxidase can also be used as a quantifiable reporter gene, since a spectrophotometric enzyme assay shows where and how much it is being

expressed (Simmonds *et al.*, 2004). Transgenic plants expressing OxO have been shown to be resistant to fungal pathogens *in vivo* (Liang *et al.*, 2001; Livingstone *et al.*, 2005). OxO may be particularly well suited for use against DED, as De Rafael *et al.* (2001) showed that H₂O₂ significantly slowed growth of *O. novo-ulmi*, and it is also part of the natural defense response in the DED-resistant *U. pumila*. *O. novo-ulmi* has not been tested for production of oxalate that could then be converted to H₂O₂, but many other ascomycetous phytopathogens are known to produce oxalate (Foster, 1951; Dutton and Evans, 1996), and the potential benefits for use of OxO as a transgene should warrant further investigation. OxO has also shown promise for *in vivo* use against insect pests, so simultaneous control of the fungus and vector may be possible. Specifically, European corn borer feeding and larval growth were both reduced when OxO was expressed in corn leaves (Ramputh *et al.*, 2002).

3.4 Public Perceptions and Economic Consequences

Informal surveys have indicated that public perception of transgenic heritage trees for restoration purposes may be higher than that of transgenics used to increase crop yields (W. Powell, personal observations; Fenning *et al.*, 2005). The vascular-specific promoter used in this research was cloned from the American chestnut tree, and if appropriate disease-resistant genes and regulatory sequences were found in other trees, public acceptance may be even greater.

Black Walnut

**Charles H. Michler, Paula M. Pijut, Richard Meilan, Gurpreet Smagh, Xiaoyu Liang
and Keith E. Woeste**

Hardwood Tree Improvement Regeneration Center, Purdue University, West Lafayette, IN, USA

1. INTRODUCTION

1.1 History, Origin, and Distribution

Black walnut (*Juglans nigra* L.), also known as eastern black walnut or American walnut, is a premier, commercial, hardwood timber (and nut) species. The genus *Juglans* is derived from the Roman name *Jovis glans* meaning “nut of Jove (Jupiter)” (Goodell, 1984), and *nigra* meaning “black” in reference to the dark wood, bark, and nut husks. Ancient fossil records date walnuts to the middle to upper Cretaceous period (Elias, 1980). Native to the deciduous forests of the eastern United States from Massachusetts to Florida and west to Minnesota and Texas, and occurring naturally in southern Ontario, Canada, black walnut is seldom found in pure stands, but rather in association with five mixed mesophytic forest cover types: (1) sugar maple (*Acer saccharum* Marsh.); (2) yellow poplar (*Liriodendron tulipifera* L.); (3) yellow poplar-white oak (*Quercus alba* L.)—northern red oak (*Quercus rubra* L.); (4) beech (*Fagus grandifolia* L.)—sugar maple; and (5) silver maple (*Acer saccharinum* L.)—American elm (*Ulmus americana* L.) (Williams, 1990). Historically, the bark of black walnut was used by several Native American tribes, including the Cherokee, Delaware, Iroquois, and Meskwaki, in tea as a cathartic, emetic, or disease remedy agent, and chewed or applied for toothaches, snake bites, and headaches (Moerman, 1998, 2003).

Caution: the bark should be used cautiously in medicine because it is poisonous. The Cherokee, Chippewa, and Meskwaki also used the bark to make a dark brown or black dye (Moerman, 1998, 2003). The Comanche pulverized the leaves of black walnut for treatment of ringworm, the Cherokee used leaves to make a green dye, and the Delaware used the leaves as an insecticide to dispel fleas (Moerman, 1998, 2003). The nut meats were also a food source for Native Americans, and the nuts are still consumed today by people and are an important food source for wildlife, especially squirrels (Goheen and Swihart, 2003). A toxic chemical “juglone” (5-hydroxy-1, 4-naphthoquinone), naturally occurring in the leaves, buds, bark, nut husks, and roots of black walnut, is a highly selective, cell permeable, irreversible inhibitor of the parvulin family of peptidyl-prolyl *cis/trans* isomerases (PPIases) and functions by covalently modifying sulfhydryl groups in the target enzymes (Henning *et al.*, 1998; Chao *et al.*, 2001). Certain plants, especially tomato, apple, and several conifer species, are adversely affected (allelopathy; foliar yellowing, wilting, and even death) by being grown near the roots of black walnut trees (Goodell, 1984; Dana and Lerner, 1994). Horses can contract acute laminitis, an inflammation of the foot, when black walnut wood chips or sawdust is used for stall bedding or stables, and paddocks are located too close to walnut trees (Galey *et al.*, 1991).

1.2 Botanical Description

Black walnut is a member of the family Juglandaceae, section *Rhysocaryon* (Manning, 1978). In general, *J. nigra* will not cross with species in the sections *Cardiocaryon* or *Trachycaryon*, but *J. nigra* will cross with *J. ailantifolia* (*Cardiocaryon*) (Williams, 1990). *J. nigra* will also hybridize to some extent with other *Juglans* species (*Dioscaryon* and *Rhysocaryon*) and one hybrid is recognized: *J. nigra* \times *J. regia* = *J. \times intermedia* Carr. (USDA-NRCS, 2004). *J. nigra* is the largest and the most valuable timber tree of all the *Juglans* species, and it is hardy to USDA (United States Department of Agriculture) hardiness zone range of four to nine (Dirr, 1998). Black walnut is a large tree and on good sites may attain a height of 30–38 m, diameter of 76–120 cm, and can exceed 100 years of age (Williams, 1990; Dirr, 1998; USDA-NRCS, 2004). Black walnut is shade intolerant, and control of competing vegetation is especially important in new plantations for the first 3–4 years. Black walnut grows best on moist, deep, fertile, well-drained, loamy soils; although it also grows quite well in silty clay loam soils or in good agricultural soils without a fragipan (Williams, 1990; Cogliastro *et al.*, 1997). These sites include coves, bottomlands, abandoned agricultural fields, and rich woodlands. Black walnut forms a deep tap root, wide-spreading lateral roots, and has been cultivated since 1686. Black walnut is monoecious with male and female flowers maturing at different times (McDaniel, 1956). Staminate catkins (5–10 cm) develop from axillary buds on the previous year's wood and appear as small, scaly, conelike buds, and the female flowers occur in two to eight flowered spikes borne on the current year's shoots (Brinkman, 1974; Williams, 1990; Flora of North America Editorial Committee, 1993; Dirr, 1998). The female flowers more commonly appear first (protogyny) and flowering occurs with or shortly after the leaves. Because flowering is dichogamous, self-pollination is unlikely, thereby promoting outcrossing. The fruit is a drupelike, furrowed nut enclosed in a thick, indehiscent yellowish-green husk that develops from a floral involucre (Brinkman, 1974). Fruits are subglobose to globose, rarely ellipsoid, 3.5–8 cm, warty, with scales and capitate-glandular hairs (Flora of North America Editorial Committee, 1993). The fruit

occur singly or in clusters of two to three and are edible, sweet, oily, and high in protein (Reid, 1990). The nut is subglobose to globose, rarely ellipsoid, 3–4 cm, very deeply longitudinally grooved, and the surface between the grooves is coarsely warty (Flora of North America Editorial Committee, 1993). Leaves are alternate, pinnately compound, 30–60 cm long, with 9–23 leaflets, nearly glabrous and somewhat lustrous dark green, pubescent and glandular beneath, with petioles 6.5–14 cm long covered with glandular hairs (Flora of North America Editorial Committee, 1993; Dirr, 1998). Black walnut stems are stout, densely gray-downy, smooth and reddish buff; have a chambered light brown pith (paler than that of butternut, *Juglans cinerea*), and a distinctly notched leaf scar. Terminal buds are ovoid or subglobose, 8–10 mm long, and weakly flattened (Flora of North America Editorial Committee, 1993). Lateral buds are smaller, often superposed, and grayish in color. *J. nigra* has a dark gray or brownish bark, deeply split into narrow furrows and thin ridges, the ridges are chocolate in color when cut, forming a roughly diamond-shaped pattern. The wood of black walnut is semi-ring porous (Miller, 1976), with the sapwood nearly white and the heartwood varying from light to dark brown. Vessel element lengths average 517–666 μm , fiber-tracheid lengths 1204–1634 μm , ray height 229–355 μm , and pore diameter averages 170–202 μm (Miller, 1976). The wood is heavy, hard, strong, normally straight grained, and has good resistance to shock (Forest Products Laboratory, 1999). The chromosome number of black walnut is $2n = 32$ (Woodworth, 1930). Black walnut trees produce seed at about 12 years of age, with good seed crops occurring every 2–3 years (Brinkman, 1974). Seeds of black walnut, like most *Juglans* spp., have a dormant embryo, but dormancy can be broken by fall sowing or by moist prechilling of seeds at 1–5°C for 3–4 months (Brinkman, 1974; Williams, 1990). Commercial propagation is by seed or grafting of selected cultivars (Reid, 2001).

1.3 Economic Importance

Black walnut is one of the largest hardwood trees found in the United States, and is valued economically and ecologically for its wood and

edible nuts. Quality black walnut wood demands high market prices for many uses including furniture, veneer, cabinets, interior architectural woodwork, flooring, and gunstocks. Black walnut wood with figured grain demands even higher market prices. Curly and wavy figure can produce interesting characteristics in veneers, and these can arise from walnut butts, crotches, burls or in rare cases, occur throughout the wood of the whole tree. The nut is an important food source for wildlife and is also consumed by humans. The majority of black walnut trees occur in natural stands, with walnut plantations (approximately 13 800 acres) accounting for 1% of all the black walnut volume (ft³) in the United States (Shifley, 2004). There are 11 states that currently have the greatest volume of black walnut growing stock on timberland, and these include Missouri, Ohio, Iowa, Indiana, Illinois, Tennessee, West Virginia, Kansas, Pennsylvania, Virginia, and Michigan (Shifley, 2004). Since the last (1997) comprehensive inventory and summary of the black walnut resource in the eastern United States, the number and volume of black walnut trees has increased, except in Michigan, Virginia, and Pennsylvania where walnut volume is level or decreasing (Shifley, 2004). In addition to the multimillion dollar US market consumption of walnut wood, for the period 2001–2005, the United States exported walnut lumber to 68 area/countries (80 069.9 m³; \$60 110 242; averages for this period) and walnut logs to 51 area/countries (88 814.2 m³; \$57 693 282; averages for this period) (USDA-FAS, 2006). Black walnut yields edible nuts that are used in baking (cookies, cakes, etc.) and ice cream products. The Hammons Products Company (Stockton, MO; <http://www.black-walnuts.com>) is the world's premier processor and supplier of American black walnuts for both food and industrial uses. The Lodi Nut Company (Lodi, CA; <http://www.lodinut.com>) is a large retail supplier of bulk black walnut nuts and gift baskets. Selection of black walnut trees for nut quality and production has developed slowly over the years, but over 700 cultivars have been named and the percent of edible kernel has improved to over 34% (Reid, 1990; Reid *et al.*, 2004). Black walnuts are low in saturated fats (3.4 g per 100 g edible nut), have zero cholesterol, and are high in polyunsaturated (35.1 g per 100 g edible nut) and monounsaturated fats (15 g per 100 g

edible nut) (USDA-ARS, 2004). Black walnuts are also a good source of protein (24.1 g per 100 g edible nut) and fiber (6.8 g per 100 g edible nut) containing low levels of sugar (1.1 g per 100 g edible nut) (USDA-ARS, 2004). Processed black walnut shell is a soft grit, durable, nontoxic, biodegradable abrasive product used for many industrial purposes. It is used for metal cleaning and polishing, in oil well drilling, for plaster effect in paints, as filler in explosives, and as a grit agent in soaps, cosmetics, and dental cleansers (Thomas and Schumann, 1993). Because of the various economic values mentioned above, breeders have been interested in employing conventional breeding to improve some of the economic traits.

1.4 Traditional Breeding: Breeding Objectives, Tools and Strategies, and Achievements

The majority of black walnut conventional breeding has focused on improvement of the species for timber traits and these activities have mostly occurred in the Midwest. Although monoculture plantations of black walnut for timber production date from the 1600s, modern efforts at genetic research were initiated in the early 1950s (Minckler, 1952, 1953; Wright, 1954). In the last 50 years, genetic research has included studies of breeding methods, development of breeding resources, genetic variance, heritability and selection age, adaptation, and use of hybrids.

Height and diameter growth are the most studied traits in black walnut and these traits can help predict adaptation to a site. In early generations of selection, heritability estimates for these growth traits are very high. It was reported by Rink and Clausen (1989) that results of three progeny tests at age 13 showed heritability (h^2) for height was about 0.41, and there were significant family \times site interactions. Kung *et al.* (1974) found h^2 for height growth was approximately 0.4, although Rink (1984) and Beineke (1974) indicated a value slightly higher ($h^2 = 0.55$). Heritability of diameter growth is in the same range as height ($h^2 = 0.35$ – 0.65) (Beineke and Stelzer, 1991; Rink and Kung, 1995). However, Woeste (2002) found a lower value ($h^2 = 0.28$)

based on a 35-year-old progeny test. Hammitt (1996) and Rink (1997) found that heritability of this trait was near zero at outplanting, increased over the first 10 years, and stabilized around age 15.

Estimates of the heritability of tree form range from 0.4 to 0.5 (Beineke, 1989; Beineke and Stelzer, 1991). Estimates for the other heritability factors include foliation date (0.92), defoliation date (0.73), sweep (0.32), number of crooks (0.24), branch angle (0.20), and branch number (0.41) (Beineke, 1974). Heritability estimates for multiple stems (0.18), leaf drop date (0.13), insect damage (0.27), and leaf angle (0.32) were reported by Bey (1970).

Walnut anthracnose causes foliage to senesce and trees to defoliate earlier than more resistant genotypes. Anthracnose resistance may be highly heritable (Funk *et al.*, 1981; Woeste, 2002), and this could be important in extending the growing season and thus the growth of black walnut. Attempts to associate anthracnose resistance with growth were not conclusive in earlier published studies (Todhunter and Beineke, 1984), but recently, control with fungicides has shown to increase late season growth in industrial plantations (Pardillo, personal communications).

The heritability of important wood quality traits such as heartwood formation and color and wound recovery require destructive sampling of mature trees. Nelson (1976), Rink (1987), and Woeste (2002) all report that heartwood area has a moderate to high heritability ($h^2 > 0.4$), possibly because this trait is strongly associated with tree vigor (Woeste, 2002). Rink (1987) was unable to find any genetic component to heartwood color.

The rotation age for black walnut is more than 60 years, thus selection of juvenile trees for their anticipated rotation-age value is essential. Juvenile-mature correlations and rank correlations for height and diameter growth based on progeny tests were reported by various authors (McKeand *et al.*, 1979; Rink, 1984; Beineke, 1989; Rink and Kung, 1995). In general, these studies found family selection for high heritability traits of height and diameter growth can begin by about age 8, but that within family selection should be delayed until after age 12. The optimal age for selection depends on thinning schedules and site quality, as these factors influence selection intensity,

intertree competition, and trait heritability (Kung, 1973).

Provenance trials to measure the effects of long-distance seed movement have been a fundamental part of black walnut improvement. These provenance trials were established to characterize regional genetic variability and to determine the relationship between the latitude of seed sources and tree growth. The underlying rationale was that trees from southern sources would leaf out earlier and lose their leaves later than trees from more northern latitudes. Longer growing seasons, in turn, would translate into faster growth. Frost injury, which can cause poor form, and dieback from winter injury, were considered potential drawbacks to the use of southern seed sources. Reports by Bey and Williams (1975) indicated that trees from provenances south of the planting site would perform well compared to local sources. Bey (1979, 1980), and Bresnan *et al.* (1992, 1994) refined this analysis. Results from a large number of provenance studies provide a general guideline that recommends planting of seeds from sources 200 miles (322 km) to the south for optimal growth. The use of grafted trees to evaluate site effects and adaptability is only now underway (Woeste and McKenna, 2004).

Rink *et al.* (1989) were able to determine the mating system parameters for black walnut using allozyme systems. The goal of the research was to determine the level of inbreeding and outcrossing of black walnut in native stands and the allocation of genetic variance at marker loci among and within populations. Rink found that black walnut had a high outcrossing rate (about 90%) and was highly heterozygous based on eight loci. The 26 maternal trees in the study were significantly more heterozygous than their progeny, and the authors suggested this might have been caused by selection against inbred progeny. These findings were substantiated by later research (Rink *et al.*, 1994; Busov *et al.*, 2002). These later studies also showed that the mating parameters of black walnut seed orchards were similar to those found in wild stands, and that as much as 94% of the variance in the isozyme marker loci was distributed within populations, i.e., that very little differentiation among populations could be detected at the level of allozymes. Fjellstrom (1993) found high levels of heterozygosity in black walnut using restriction fragment length polymorphisms, and Woeste has

indicated that black walnut is highly heterozygous at microsatellite loci (Woeste *et al.*, 2002) as well.

Interspecific *Juglans* hybrids have unusual vigor. The “Royal” hybrid (*J. hindsii* × *J. nigra*) has been impractical in the Midwest because of poor cold tolerance, but in milder climates such as California and Pacific Northwest, it appears to have excellent potential as a timber tree (Forde and McGranahan, 1996). Hybrids between the *J. nigra* × *J. regia* known as *J. × intermedia* Carr. have attracted the most interest in the United States (Wright, 1966; Funk, 1970) and Europe (Hussendorfer, 1999; Germain, 2004). Funk (1970) summarized the hybridization research of McKay (1965) and others who found that while *J. × intermedia* had variable vigor, it was nearly sterile, and all attempts to restore fertility through the production of amphidiploids failed. The clonal deployment of *J. × intermedia* Carr. has occurred in France, and the possible uses of seedling hybrid rootstock for timber production in the Midwestern United States was discussed by Woeste and McKenna (2004). In addition, they cite the potential of *J. nigra* × *J. major* hybrids as a rootstock for drier sites. The identity and parentage of *Juglans* hybrids can be verified using intersimple sequence repeats (Potter *et al.*, 2002).

1.5 Limitations of Conventional Breeding and Rationale for Transgenics

In some cases, genes for traits of interest do not exist within the native population of black walnut or addition of the trait requires introgression of several or more genes at the same time in order to achieve expression of the trait. Some examples for black walnut are resistance to glyphosate and sulfometuron methyl herbicides, flowering control or sterility, early heartwood formation, and curly grain. Genes for some of these traits have been described and methods have or will be developed in order to insert them into the black walnut genome. In other cases, genes for some traits have yet to be identified and characterized. In theory, using transgenic technologies, foreign genes can be inserted, plants selected, and the transgenes expressed that will result in elite clones with the new traits that could not be accomplished with breeding.

2. DEVELOPMENT OF TRANSGENIC WALNUTS

2.1 Review of Prior Literature

Fang and Wang (2000) achieved somatic embryogenesis from black walnut tissues and developed an *Agrobacterium*-mediated transformation system to insert genes into the somatic embryos. In this research, immature embryos and leaf explants from black walnut grown in China were acquired 1 month after pollination. Woody plant medium (WPM) developed by Lloyd and McCown (1981) with 2.0–6.0 mg l⁻¹ 2,4-D (2,4-dichlorophenoxyacetic acid) and 0.1–0.5 mg l⁻¹ KT (kinetin) was used to induce callus formation, which occurred on the explants after 1 month of culture. Then WPM with 0.1–0.2 mg l⁻¹ 2,4-D, 0.1–0.5 mg l⁻¹ KT, and 1 mg l⁻¹ hydrolyzed casein was used to induce the formation of somatic embryos from callus, and different stages of somatic embryos developed on the medium. Microshoot and root development were observed from the somatic embryos when cultured on WPM basal medium. The induction ratio of callus and somatic embryos from immature embryo explants (67.7% and 25.36%, respectively) were higher than that from immature leaf explants (15.4% and 2.4%, respectively), thus immature embryo explants were used to develop the genetic transformation system. *Agrobacterium*-mediated transformation was carried out following the method by McGranahan *et al.* (1988), but somatic embryo pieces around 5 mm and an *Agrobacterium* strain containing binary vector with *uidA* and *nptII* (neomycin phosphotransferase II) genes were used for infection. Co-cultivation was carried out on somatic embryo induction medium for 2–3 days, following by selection on the same medium with 100 mg l⁻¹ kanamycin and 500 mg l⁻¹ cefotaxime. β -glucuronidase (GUS) staining was used to assist selection of transformed embryos. Completely transformed somatic embryos were acquired after five generations of secondary embryo production, but the selection efficiency reached 90% by the third to fourth generation. Plantlets with shoot and root were developed after 20 days cultured on WPM with 0.5 mg l⁻¹ BA (benzyladenine), 0.2 mg l⁻¹ IBA (indole-3-butyric acid), 1.0 mg l⁻¹ GA (gibberellic acid), and 100 mg l⁻¹ kanamycin. Transgenes were verified by

polymerase chain reaction (PCR) and southern hybridization of transgenic embryos and plantlets. Comparison experiments with different stages of somatic embryos indicated that globular and torpedo embryos had higher transformation and secondary embryo production efficiency than cotyledonary embryos and callus, and it was very difficult to induce secondary embryos from mature cotyledonary embryos.

Kanamycin resistant black walnut transgenic lines were developed by Bosela *et al.* (2004). In this project, somatic embryos were induced from immature zygotic embryo cotyledon pieces of open-pollinated elite black walnut trees. More than 40 lines of somatic embryos of different genotypes with different induction media were established, some of which are still constantly maintained *in vitro* on a 3–5-week subculture cycle on MS (Murashige and Skoog) or DKW (Driver and Kuniyuki) media. Globular and cotyledonary embryos were induced on media without or with 2,4-D. Globular and cotyledonary embryos were proliferated by repetitive secondary embryo production, where the secondary embryos were directly attached to the parent somatic embryo or lacked obvious connection. Different *Agrobacterium* strains containing different binary vectors harboring *uidA* (with or without intron) and *nptII* genes were used to infect immature cotyledonary somatic embryos 1.0–1.25 cm in width for 20–30 min. Co-cultivation was carried out on basal medium with 100 μ M acetosyringone for 60 h in the dark, following by several washes with and culture on antibiotic containing media. Selection were carried out on medium with 250 mg l⁻¹ kanamycin for one experiment, and T-DNA transfer ratio of 75–100% was obtained for 10 genotypes as indicated by GUS staining, but less than 10% of the primary embryos produced secondary embryos on the selection media. In another experiment (Smagh, 2005), five different genotypes were infected with *Agrobacterium*, with T-DNA transfer ratio from 54% to 100% among genotypes. Secondary embryo production on 100 mg l⁻¹ kanamycin was 55% for infected embryos. After three generations of secondary embryo production, completely transformed embryos were obtained and verified by PCR.

In a current study to develop herbicide resistant black walnut, the selection dose of the active

ingredient of ArsenalTM has been determined for black walnut somatic cotyledonary embryos (Liang, personal communication) and construction of binary vector containing an ArsenalTM resistance gene for black walnut transformation is underway. No transformation experiments have been performed to date.

One of the critical steps in production of transgenic black walnut is to induce the transformed tissue to regenerate roots. The presence of flavonoids in walnut tissues is speculated to inhibit the adventitious rooting process, which is often crucial for propagation of clonal hardwood trees, so an antisense gene strategy was used to target the chalcone synthase (CHS), a key enzyme in flavonoid biosynthesis, and investigate how the flavonoid content could influence rooting capacity (El Euch *et al.*, 1998). In this study, cotyledons of an immature hybrid walnut (*J. nigra* \times *J. regia*) were used as explants to induce somatic embryos, which were maintained by repetitive embryogenesis on basal DKW medium. For transformation, embryos 2–5 mm in width were used for infection with an *Agrobacterium* strain containing the antisense vector that harbored a *uidA* gene with intron, a *nptII* gene, and a antisense chalcone synthase (*chs*) gene, or control vector that harbors only *uidA* and *nptII* genes. Co-cultivation occurred on basal DKW (Driver and Kuniyuki, 1984) medium for 48 h at 24 °C. DKW medium with 500 mg l⁻¹ kanamycin, 250 mg l⁻¹ cefotaxime, and 500 mg l⁻¹ tacarpen was used as selection medium. Of the first generation of secondary embryos produced after transformation, 20 out of 80 embryos stained positive in histochemical GUS tests. Embryos produced in following generations were maintained as homogeneous lines, and 13 lines transformed with the antisense vector were obtained. A control transformed line and an untransformed line were also maintained. Embryo epicotyls were placed on DKW medium with 1 mg l⁻¹ BAP (6-benzylaminopurine) and 1 μ g l⁻¹ IBA for 3 weeks to produce microshoots, which were sub-cultured four times on a 3-week cycle before been tested by various means. Northern blotting and RT-PCR were used to characterize the *chs* genes present in the hybrid walnut. CHS activity and flavonoid content were determined and six antisense lines expressed flavonoid deficiency at the mRNA (messenger-RNA) level and very low or undetectable levels

of myricitrin and quercitrin, and undetectable amounts of flavanols were found in the stems. Microshoots were tested in two ways to test rooting capability of the whole microshoot or only the stem segments. Morphological changes were noted. The rooting percentage was higher in most of the antisense lines where the flavonoid content was decreased, than in the control lines with normal flavonoid content. Auxin content was determined, but no variation was detected between antisense and control lines.

2.2 Methods Developed: *Agrobacterium* Strains and Genetic Construct Development

For *Agrobacterium* transformation, several different strains have successfully been used along with various constructs. In the first case, El Euch *et al.* (1998) used the disarmed C58/pMP90 *Agrobacterium* strain, pKY/GIN/AS.B as the antisense *chs* vector, pKY/GIN as the control vector, and pKY/GIN/AS.B was placed between nopaline synthase (*nos*) promoter and terminator; *uidA* with a plant intron placed between cauliflower mosaic virus (CaMV) 35S promoter and NOS terminator. A 400 bp *chs* gene fragment (CHS.B) was placed in reverse direction with duplicated CaMV 35S promoter and followed by *rbcs* terminator. Fang and Wang (2000) used the EHA 105 *Agrobacterium* strain that contained pMOG410 with *nptII* and *uidA* selection and marker genes (with intron) in the T-DNA region. Bosela *et al.* (2004) used the GV3101/pMP90 *Agrobacterium* strain with two different binary vectors, pBI121 and pBISN1, in different experiments. Using the pBI121 vector, *nptII* was driven by *nos* promoter and *uidA* (without intron) was driven by CaMV 35S promoter. With the pBISN1 vector, *nptII* was driven by the *nos* promoter; but *uidA* (with intron) was driven by a “super promoter” provided by S. Gelvin at Purdue University.

2.3 Selection of Transformed Tissue Using Antibiotic Resistance

In order to select transformed tissue in association with untransformed plant tissue for generation of transgenic black walnut, it is necessary to have a

selectable marker gene. The selective marker gene is inserted during the transformation process along with the donor gene into the donor genome. With black walnut, the kanamycin (*nptII*) resistance gene has been used most often as the selective marker.

Transgenic tissue is selected using the *nptII* gene and the *uidA* gene is inserted so that the transformation event can be later verified (Bosela *et al.*, 2004; Smagh, 2005). In the black walnut system, somatic embryos used as the target for transformation are induced to generate secondary somatic embryos on the cotyledon surface. Since it has been found that secondary embryogenesis originates from one single cell with walnut species (Polito *et al.*, 1989; Aly *et al.*, 1992), then transgenic cells have the potential to produce a completely transgenic secondary embryo. A sublethal kanamycin dose, the rate at which untransformed embryos produce no or only a few secondary embryos, has been used to select putative transgenic embryos (Smagh, 2005). At this particular dose, after transformation, secondary embryos are produced from transgenic tissue. Transformed walnut cells will have obtained kanamycin resistance while maintaining the ability to produce secondary embryos.

Two different strategies can be followed when choosing doses to use for selection pressure. A high selection pressure can be applied, if the repetitive secondary embryogenesis system is highly productive and selection of only transformed tissue is the objective. The disadvantage is that some incompletely transformed or chimeric embryos might not be able to survive at a high antibiotic dose. In the second approach using low selection pressure, even partially transformed embryos will produce secondary embryos from transformed cells or patches of tissue. This will ensure that partially and completely transformed secondary embryos will survive and produce putatively transformed secondary embryos. In this latter case, there will be some escapes, which can be killed by antibiotic selection during later culture on medium containing kanamycin. Nontransformed tissue can also be detected by histochemical GUS assays (Smagh, 2005), but this is a destructive procedure.

If the transformation event occurs in only one cell and the transformed cell differentiates and multiples to form a secondary embryo,

the result will be a completely transformed embryo. It can be cultured to produce secondary embryos to start a new transgenic line of walnut embryos. If transformation event occurs after cell differentiation process, then secondary embryos will not be completely transformed, because some cells will have originated from untransformed cells, resulting in chimeric embryos. Using chimeric embryos, transformed cells within the chimeric somatic embryo will eventually generate completely transformed secondary somatic embryos when selection is continual on kanamycin-containing medium. Only at this point can these embryos be used to start a new transformed embryo line.

2.4 Regeneration of Whole Plants

Maturation and germination of black walnut somatic embryos was documented initially by Deng and Cornu (1992). The authors were able to germinate 45% of the embryos into complete plantlets by maturing them with cold treatment for 2 months or desiccation for 3–5 days. Addition of GA to germination medium increased germination. Although acclimatization in the greenhouse was not tried, survival of plantlets was observed after transplanting into peat and vermiculite. Routine production of complete plants has been reported in other *Juglans* species, but not much success has been achieved in black walnut. Smagh (2005) was able to germinate transformed black walnut somatic embryos, although few of them had elongation of the shoot apex. Somatic embryos (1.5–2.0 cm in length) were first desiccated in 95% relative humidity at 25°C for 3 weeks and then placed on germination medium (half basal DKW with 1% sucrose and 100 mg l⁻¹ kanamycin) in petri plates in light for 3 weeks. Sixty-nine percent of the embryos germinated with roots only and with 2% of the embryos, shoot initiation was observed. After 3 weeks, germinated embryos with root elongation were transferred to shoot development medium (basal DKW + 2% sucrose, 20 mg l⁻¹ adenine sulfate and 2.5 µM zeatin) in 200 ml jars. After 4 weeks in culture, 22% had shoot elongation. The remaining explants developed callus on the roots and died. Embryos with both root and shoot elongation did not show any further elongation and were converted

into shoot cultures by discarding the roots and transferring the remainder of the explant to DKW medium containing higher concentrations of zeatin (6.25 µM). In studies by other authors (Deng and Cornu, 1992; Tang *et al.*, 2000) they used embryo explants at earlier stages of development, which might lead to better germination. New experiments are being designed by X. Liang (personal communication) to look at effect of cold treatment before germination and use of somatic embryos that have not been exposed to extended time to the *in vitro* environment.

2.5 Testing: Transgene Insertion, Transgene Function, and Whole Plant Testing

Transformed trees need to be tested at the molecular level, in the greenhouse and in field tests to confirm gene insertion and gene function before propagating the trees for commercial production. Expression of inserted genes is necessary to determine gene function because T-DNA insertions into the nuclear genome occur randomly. Random insertion can cause the transgene to be nonfunctional or it can disrupt the expression of another gene through insertion in the functional area of that gene in the genome. In addition, if the transgene is inserted in the wrong orientation, this improper insertion may cause the transgene to become nonfunctional.

The most accepted method for detection of transgenes in the target cells at molecular level is through PCR. A primer or unique DNA sequence of approximately 15–20 nucleotides, which is only present in the transgene, will amplify a particular region of the transferred gene and this amplified product can be detected using agarose gel electrophoresis. This method is very simple and easy, but it cannot detect the number of copies of the transferred gene. Southern hybridization can detect the number of copies of transgenes inserted into genomic DNA. In this method, a labeled DNA sequence fragment is hybridized to genomic DNA fixed on a membrane. Each inserted copy of the transgene in genomic DNA will be detected on membrane in an appropriate background. Both PCR and southern hybridization methods should be performed both with somatic embryos and plant leaves to insure there are no escapes during selection procedure.

Further tests of gene function are required to insure that no essential part of the transgene has been truncated. This can be achieved by testing the expression of a foreign gene inserted along with the desired gene. A selectable marker such as *uidA* can be detected *in vitro* by culturing putatively transformed embryos on kanamycin medium and germinating these embryos in kanamycin containing medium. All embryo cells lacking this gene will die. A destructive method for testing transgenics and gene insertion into plant cells is the histochemical GUS assay. If the complete *uidA* gene is integrated into plant genomic DNA, indigo coloration will appear in embryos treated with X-Gluc solution containing substrate for β -glucuronidase enzyme made by *uidA* gene. Chemical reaction taking place will cause indigo coloration, which can be detected visually or under a light microscope, which will be a positive indicator of gene expression and proper insertion of T-DNA region into plant genomic DNA.

Field testing of transgenics is necessary to determine if transgene expression is stable over the long term, if the level of gene expression is at a sufficient level to warrant commercial production of the bioengineered tree, and if the gene insertion has caused any unexpected phenotypic changes or changed the species ecological fitness.

2.6 Regulation of Transgenic Walnuts

USDA's Animal and Plant Health Inspection Service (APHIS) monitors release and regulation of transgenic plants. APHIS has considerable experience in assessing annual row crop plants for agricultural and environmental safety, but there are no rules and regulations for transgenic trees for commercial deployment. Recent advances in tree genetics and biotechnology has accelerated the pace of transgenic tree production and the issue of regulating open-pollinated transgenic trees is currently being addressed. Regulations for open-pollinated transgenic tree species such as black walnut are currently being formulated. APHIS has asked for public input on this issue and the agency is likely to publish directions in the near future.

An important issue that will be considered for deployment of transgenic black walnut is the escape of transgenes to sexually compatible species outside a managed site. In case of herbicide-

resistant trees, spread of herbicide resistance genes into compatible species of trees could make these trees weedy. Also, before receiving approval for deployment, controlled field trials would be required and guidelines could be different from annual row crops due to large size, perennial nature, and outcrossing capacity of trees.

In addition to APHIS that regulates plants that could become agricultural pests, black walnut transgenics could either be regulated the Food and Drug Administration (FDA) and Environmental Protection Agency (EPA). FDA would regulate genetically engineered black walnut used for foods, drugs, cosmetics, and medical devices and EPA would regulate bioengineered trees expressing pesticidal properties (Anonymous, 2003). There is speculation that APHIS might publish regulations that would require sterility in trees and the deployment of transgenic trees would not be allowed to contain any foreign genes such as *nptII* or *uidA* that had been used as selectable markers.

3. FUTURE ROAD MAP

3.1 Expected Products

Applied research efforts are being focused on those traits that are most needed by growers, either for management purposes or to maintain global competitiveness. Those traits in greatest demand are likely to be made available first. Because our ability to commercialize any transgenic tree is predicated on the development of a durable confinement strategy (see below), flowering control is of the highest priority. Recent work has shown that reducing competing vegetation is one of the most important factors influencing seedling survival (Jacobs *et al.*, 2004), so herbicide tolerance is another area of emphasis. The success of forest-tree plantations is often severely hampered by animal browse (Trumbull *et al.*, 1989; Martin and Baltzinger, 2002; Jacobs *et al.*, 2004). In some areas, up to 85% of regeneration failures are the result of damage from deer (Marquis, 1981). In addition to affecting seedling development, herbivory can also have long-term effects on performance (Ward *et al.*, 2000). Although this concern is not currently getting much attention, it will become increasingly important over time. Finally, being able to manipulate the formation

of figured wood and heartwood will add value to the timber produced by walnut, so genes affecting these traits are also being investigated.

3.2 Risks and Concerns

Public acceptance will be needed before transgenic trees can be deployed commercially. To enhance our chances of achieving this outcome, it is incumbent upon plant scientists who are developing these biotechnologies to cooperate with their colleagues in the behavioral and social sciences so they can conduct studies concerning the societal, economic, and political aspects of their use. These studies should determine the level of public knowledge of tree biotechnology, and evaluate how this awareness will impact citizens and policymakers in the context of resource availability and global competitiveness. Without this type of interdisciplinary activity, it is unlikely that we will be able to take advantage of advancements resulting from the genomics revolution that is currently underway in plant biology.

A key aspect of public and regulator acceptance is transgene confinement. Before genetically engineered trees can be commercialized, APHIS, which has overarching regulatory authority over the deployment of transgenic trees, is likely to require a strategy to mitigate the risk of transgene spread and persistence in the environment. With this in mind, researchers worldwide are attempting to genetically engineer flowering control in trees (Meilan *et al.*, 2001; Lemmetyinen and Sopanen, 2004). By manipulating the genes involved in the control of floral development, it should be possible to engineer reproductive sterility. This approach may help alleviate public and regulatory concerns over the commercialization of transgenic trees containing other introduced, desirable traits. Blocking the production of sexual propagules (e.g., pollen and seeds) or flowers entirely is also likely to promote vegetative growth (Eis *et al.*, 1965; Tappeiner, 1969; Teich, 1975), leading to shorter harvest rotations. Moreover, flowering-control research could lead to ways for either delaying the onset of flowering, which could itself serve as a confinement strategy, or shortening their juvenile periods, which could lead to shorter breeding cycles.

3.3 Expected Technologies

In order to genetically engineer a plant, it is necessary to stably introduce a gene into the genome of an individual plant cell. The transformed cell must then be coaxed into differentiating into a whole plant, i.e., regeneration. Either process can limit our ability to recover transgenic plants. Although efficient transformation and regeneration systems have been developed for poplars (species within the genus *Populus*) (DeBlock, 1990; Confalonieri *et al.*, 1995; Han *et al.*, 2000; Meilan and Ma, 2006), most other tree species, including black walnut, are refractory with respect to one or both processes. Protocols originally developed for Persian walnut (*J. regia* L.) (McGranahan *et al.*, 1988, 1990; Dandekar *et al.*, 1998; Escobar *et al.*, 2000; Breton *et al.*, 2004) were later applied to black walnut (Bosela *et al.*, 2004), but the efficiency with which transgenic plants were recovered from the latter was low.

One limitation of *Agrobacterium* transformation is the restricted host range of this bacterium; many plants, especially various tree species, remain highly recalcitrant to transformation. Recent breakthroughs in transformation technology have permitted *Agrobacterium*-mediated transformation of some varieties of rice and maize, both of which had been notoriously difficult to transform. It is likely that knowledge gained from transforming monocotyledonous plants can be utilized to develop more efficient systems for trees such as black walnut.

Over the past 10 years, the S. Gelvin (2000, 2003) laboratory at Purdue University has investigated the role of plant-host genes involved in *Agrobacterium*-mediated plant transformation. They have identified more than 125 of these genes in the model plant *Arabidopsis thaliana* (Zhu *et al.*, 2003). In some cases, overexpression of these genes in *Arabidopsis* increases the frequency of transformation (Mysore *et al.*, 2000; Yi *et al.*, 2002, 2006; Hwang and Gelvin, 2004). Using what has been learned with this model plant system, it should now be possible to make rapid progress with other plants, including trees.

Currently, immature zygotic embryos are used as starting materials for establishing black walnut tissue cultures. Embryogenic calli derived from these explants are, in turn, co-cultivated with *Agrobacterium*. Newly transformed cells are then

hormonally induced to differentiate into somatic embryos. There are two complications associated with this approach. First, there is no way of knowing *a priori* how an individual line will perform *ex vitro*. Thus, lines must be propagated, acclimated, and grown in soil prior to transformation, in order to ensure that the best lines are being used as starting material for transformation. Second, embryogenic masses often begin to differentiate into somatic embryos prior to being transformed. This leads to the production of chimeric plantlets, which are only partially transformed. To overcome this obstacle, successive generations of somatic embryos must be induced in order to recover fully transformed plants. This is a very costly procedure. To avoid both of these difficulties, research efforts should be focused on developing a direct organogenesis system.

Prior to transformation, a selectable marker gene is physically linked to a gene that imparts a trait of interest (e.g., herbicide tolerance, insect resistance, altered wood properties, etc.). Because this marker gene often confers resistance to an antibiotic or herbicide, the cells that are actually transformed can be isolated on a medium containing the appropriate selection agent. While this method is convenient, it is also problematic. First, various selection agents can have dramatic and negative effects on regeneration. Second, the presence of a selectable marker gene is usually an impediment to gaining public acceptance of and regulatory approval for genetically engineered plants. Finally, performing subsequent rounds of transformation may not be possible because only a limited number of selectable marker genes are available.

Assuming the need for a selectable marker and for flowering control, a minimum of three transgenes will need to be inserted if only one gene of interest is introduced. In many cases, however, more than one desirable gene is sought. Because each transgene should be tested individually before being stacked, but there are physical limits to the size of T-DNA that *Agrobacterium* can insert, one must conduct successive rounds to introduce multiple traits. Given all of this, it is essential that we have a way to remove the selectable marker gene afterward.

The following three gene-excision systems have been the focus of recent research: *Cre/lox* (Russell

et al., 1992), FLP/FRT (Lyznik *et al.*, 1996), and R/RS (Onouchi *et al.*, 1995). Their vectors typically include: (1) a recombinase gene, usually under the control of an inducible promoter, and (2) recognition sites that flank the DNA targeted for removal. However, these systems are differentially effective, if at all, in various plants. Thus, it is necessary to determine which is the most appropriate for use with black walnut. For each system, one must ascertain the efficacy of the recombinase and how cleanly it excises the target. In addition, it is important to have an inducible promoter that functions reliably in the chosen host.

Recently, alternative selection systems have been developed for plants. These are based on a growth medium that lacks a substance needed for proper metabolic activity or physiological development. A particularly attractive option exploits the inability of a cell to regenerate a whole plant without the addition of a phytohormone, or its derivative, to the culture medium at a precise step in the regeneration process. For example, most plant transformation protocols rely on the addition of cytokinin to a medium that induces the differentiation of adventitious shoots or embryos from transgenic calli. The β -glucuronidase gene (GUS), a common reporter, encodes an enzyme that cleaves glucuronide residues. The glucuronide derivative of benzyladenine is biologically inactive; if it is the sole cytokinin incorporated in the induction medium, regeneration cannot occur. However, upon hydrolysis by GUS, a biologically active cytokinin is then liberated to induce regeneration. This supplement must necessarily be transitory because cytokinin can inhibit subsequent root development.

Another positive selection strategy involves inserting a gene whose product imparts a metabolic advantage to the transformed cell. For example, mannose is a sugar that plants are unable to metabolize; cells starve when grown on a medium containing mannose as the sole carbon source. When taken up by the cells, this sugar is phosphorylated by a native hexokinase. However, plants lack a native phosphomannose isomerase gene, which encodes an enzyme that catalyzes the conversion of mannose to a useable six-carbon sugar (Joersbo *et al.*, 1998). Similarly, xylose isomerase, another enzyme that plants normally lack, is able to convert xylose to a sugar that can be utilized (Haldrup *et al.*, 1998). Regeneration

protocols that exploit positive selection strategies such as these are up to 10-fold more efficient than those that rely on more traditional, negative selection strategies (i.e., antibiotic or herbicide resistance).

3.4 Political and Economic Consequences

The current costs and burdens associated with regulatory agencies in the United States (Meilan, 2006) are having a strong negative effect on the development of the forest biotechnologies by academic and industrial researchers. Revisions in the current system are needed to encourage investment in transgene-based innovations, thus facilitating the production of improved varieties (Bradford *et al.*, 2005). Suggested changes include (1) developing a regulatory system that is based on phenotype rather than the method used to produce it, following long-standing National Academy of Science recommendations (National Research Council, 1989, 2000, 2002); (2) eliminating personal liability for academic researchers conducting approved research; and (3) establishing a means for early evaluation of the benefits and risks of gene dispersal that allows certain types of long-term field trials, similar to what is currently being done for conventional breeding programs.

Because of recent advances, the technology for creating transgenic trees is much more advanced than the research that evaluates their ecological impacts. A comprehensive, interdisciplinary scientific approach that combines experimental results with model projections is badly needed. The knowledge we acquire from this work will inform the public debate, and must be completed before a multitude of social and regulatory issues can be clarified and resolved. Failure by the forest products sector to engage in this cooperative research could lead either to the establishment of transgenic trees with unintended consequences, or to an inability to realize the numerous advantages that this technology has to offer (Farnum *et al.*, 2006).

Although there has been considerable resistance in Europe to the use of genetically modified trees, this has not been the case in Asia. For example, there are recent reports that insect-resistant transgenic poplars have already been

commercially deployed on 300–500 ha in China (Boerjan, 2005; Sedjo, 2006). Undoubtedly, this was done first with poplar because of the ease with which it can be transformed and regenerated. Given their willingness to do this with trees that have so many wild relatives with which they are interfertile, there is no reason to believe that they would not continue with other tree species soon, without regard for environmental consequences. Although we in the United States should proceed more cautiously than that, if we do not embrace this technology, our competitiveness will continue to erode.

1. INTRODUCTION

1.1 History, Origin, and Distribution

The family Casuarinaceae is a group of 96 species of multipurpose trees and shrubs that grow naturally in Southeast Asia, Malaysia, Australia, and the Melanesian and Polynesian regions of the Pacific (Wilson and Johnson, 1989). Casuarinas are characterized by a coniferlike appearance due to morphologically distinctive foliage with the leaves reduced to tiny teeth on green, jointed, needlelike branchlets (Figures 1–3). The name Casuarina is derived from the Papuan word “kasuari”, which refers to the similarity between the drooping foliage of the tree and the feathers of the Cassowary bird. The most widely used common names for Casuarinaceae species are sheoak or she-oak. Other common names include ironwood, Australian pine, bull-oak, and beefwood.

Macrofossils from the Eocene, Miocene, and Plio-Pleistocene indicate that in the past, Casuarinaceae had a much wider distribution including New Zealand and southern South America. Fossil pollen has also been identified in southern Africa, in the suboceanic Ninetyeast Ridge, and possibly in India (Wilson and Johnson, 1989).

Casuarinaceae members are tolerant to adverse edaphic and climatic conditions and most species tolerate extreme heat. They grow in a wide range

of different environments, from tropical forests to arid woodlands and coastal dunes (Barlow, 1983). They frequently occur as pioneer vegetation at early stages of plant succession following disturbances, such as fire, landslides, volcanic eruption, and flooding. In Australia, Casuarina forests occur in all the territories and cover a total area of over two million hectares.

Three main species, *Casuarina equisetifolia*, *Casuarina glauca*, and *Casuarina cunninghamiana* have been planted outside their native habitat (National Research Council, 1984). Vast plantings of *C. equisetifolia* have been established in China along the coast fronting the South China Sea. They form a green belt that stretches for 3000 km and varies from 0.5 to 5 km in width (Zhong and Zhang, 2003). *C. cunninghamiana* has been extensively planted in Argentina and neighboring countries and in Egypt. *C. glauca* has been successfully introduced in the saline soils of Israel, Cyprus, India, Kenya, Malawi, South Africa, Egypt, and Florida (National Research Council, 1984).

1.2 Botanical Description

The family Casuarinaceae is unique among angiosperms and, having no close relatives, is assigned to an order of its own, Casuarinales (Beadle, 1981). Formerly, all species were included

Figure 1 *Casuarina glauca* shelterbelt in Egypt

in a single genus, *Casuarina*, but accumulated evidence on morphology, anatomy, cytology, biogeography, and chromosome size and number resulted in the recognition of four genera: *Allocasuarina*, *Casuarina*, *Ceuthostoma*, and *Gymnostoma*. The *Allocasuarina* and *Casuarina* genera include, respectively, 59 and 17 species; *Gymnostoma* includes 18, and only 2 species have been described for *Ceuthostoma* (Dommergues *et al.*, 1999). Morphological and chromosomal characters suggest that the least specialized genus, and therefore likely to be the most primitive

Figure 2 Plantation of *Allocasuarina verticillata* in Tunisia

Figure 3 Photosynthetic branchlet of *C. glauca*

in the family, is *Gymnostoma*, while the most specialized and diverse genus is *Allocasuarina* (Wilson and Johnson, 1989). The growth habit of Casuarinaceae ranges from woody shrubs to large trees; for example, *C. cunninghamiana*, which grows to heights of 12–30 m (National Research Council, 1984).

The chromosome number in *Allocasuarina* ranges between $n = 10$ and $n = 14$ and polyploidy is frequent. In *Casuarina* and *Gymnostoma*, the chromosome number is, respectively, $n = 9$ and $n = 8$, and there is no polyploidy (Barlow, 1983). The chromosome number has not been determined for *Ceuthostoma*.

The genome size and base composition of *C. glauca* and *Allocasuarina verticillata* were determined by flow cytometry (Schwencke *et al.*, 1998). *C. glauca* has a small genome size of $2C = 0.7$ pg (picogram), 59% AT (adenine-thymine), 40.5% guanine-cytosine (GC). *A. verticillata* has a larger genome of $2C = 1.9$ pg, 59.3% AT, 41.1% GC. These small genomes are a valuable trait for genomic and molecular studies.

1.3 Economic Importance

In the field, Casuarinaceae bears nitrogen-fixing root nodules (so-called actinorhizal nodules) resulting from association with the soil actinomycete *Frankia* (Figures 4–5) (Baker and Mullin, 1992). Due to this symbiotic association, Casuarina trees have an outstanding ability to grow vigorously on

Figure 4 Nitrogen-fixing nodules of *C. equisetifolia* observed in the field

soils that are otherwise too deficient in nitrogen to sustain plant growth. The amount of nitrogen fixed by Casuarina is comparable to the amounts fixed by legumes and their *Rhizobium* symbionts (60 kg ha^{-1} per year) and these trees contribute significantly to the N-economy of ecosystems (Diem and Dommergues, 1990). Casuarina roots also form mycorrhizal associations with arbuscular mycorrhizal and ectomycorrhizal fungi that facilitate the uptake of minerals, such as phosphorus (Diem, 1996; Duponnois *et al.*, 2003). Some species can differentiate proteoid roots; these are unique features made of tightly packed rows of rootlets, which may increase the ability of the host plant to absorb nutrients and thus tolerate

Figure 5 Two-month-old nodules of *A. verticillata* obtained *in vitro*

nutrient-deficient soils (Lamon, 2003). With the combination of the different symbionts, Casuarina is one of the best species for the reforestation of low-fertility lands. In some tropical lowland agroforestry systems, it is associated with crops such as coffee, cashew nut, coconut, groundnut, sesame, and various grain legumes to enhance their quality and growth (National Research Council, 1984).

Taken collectively, Casuarina trees have many uses (National Research Council, 1984; Diem and Dommergues, 1990). They are capable of stabilizing shifting sand dunes, stabilizing eroding hillslopes, and reclaiming marshy soils that are periodically inundated. Because of their resistance to salt-laden winds, many species such as *C. glauca* and *C. equisetifolia* are widely used to stabilize coastal sand dunes (Zhong and Zhang, 2003). They are also planted as windbreaks to protect crops. Casuarina trees have proved to be one of the most effective shelter trees during typhoons and Tsunami in Asia. Some species such as *C. equisetifolia* and its hybrids grow rapidly (a growth rate of 3 m per year has been reported in India) and have an attractive dense crown; consequently, these species are often planted as ornamental plants for urban beautification, parks and seaside resorts, and along roadsides.

Another important use of Casuarina in the tropics is the production of firewood. In comparison to other fuelwood crop species, Casuarina ranks well for calorific value in relation to wood volume (about $5000 \text{ kcal kg}^{-1}$). People in China use the stumps and even litter for fuel. Because Casuarina wood splits on drying, it is difficult to use the wood for lumber and furniture making. However, it can be used in rural construction as poles for house construction, electric poles, and the masts of boats. The wood is very hard, with a density of 1000 kg m^{-3} , and is resistant to decomposition in soil and saltwater. Thus, Casuarina poles are used in Vietnam for anchoring fishing nets in the mouths of the rivers. In India, the wood of *C. equisetifolia* is also pulped for paper, and in Madagascar, the bark is extensively used for tanning leather.

1.4 Traditional Breeding

Improving the yield and adaptability of Casuarinaceae to biotic and abiotic stresses is a

big challenge in tropical regions. Two types of approaches have been used: the first is to improve the microsymbionts (*Frankia* and mycorrhiza); the second is to develop host plants with superior provenance. However, when selection of optimal *Frankia* partners was based on the nitrogen-fixing potential of different Casuarina clones, the data obtained established that the clone effect was more important than the symbiont effect. It was suggested that this observation was linked to the large intraspecific variability of Casuarina, which results from the allogamous, monoecious (though sometimes dioecious), and anemophilous character of this tree (Sougoufara *et al.*, 1992).

Strategies for plant improvement include the selection of species and provenances, conventional plant breeding using seedlings, and techniques based on vegetative propagation and tissue culture (Duhoux *et al.*, 1996; Zhong *et al.*, 2003). Casuarina trees produce good seed crops almost every year, and regenerate easily from seed. These trees are also easy to propagate by cutting, which has the advantage of being a rapid method of perpetuating the traits of superior trees. Other methods for propagating *in vitro* plants include the use of immature female inflorescences collected from mature trees (Duhoux *et al.*, 1986).

Breeding objectives include selection of trees with improved performance under saline, waterlogged, nutrient-impovertished, drought-prone, and coastal conditions. Differences in tree susceptibility to diseases and pests (Hassan, 1990) have also triggered studies on selection of Casuarina provenances and clones (Sougoufara *et al.*, 1992). Amongst the pathogens that cause damage to the wood, bacterial wilt induced by *Pseudomonas solanacearum* has been reported in *C. equisetifolia* in India and China. Vegetative propagation and selection of Casuarina for resistance to bacterial wilt succeeded in China (Liang and Chen, 1982). Several clones with satisfactory levels of resistance to bacterial wilt and possessing fast-growing characters were obtained and propagated in large coastal areas in South China. Other pests that attack the tree include insects such as crickets and grasshoppers, defoliators (*Lymantria xyli*), stem borers (*Apate monachus*), and sap feeders (*Icerya* spp.). Major root diseases are caused by *Trichosporium vesiculorum* and *Rhizoctonia* spp. (National Research Council, 1984).

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

Casuarina plantations are faced with a number of problems including diseases and pests. In the tropics, there is also a need for trees that can tolerate salty or polluted soils, as well as drought. Long breeding cycles, large size, high levels of heterozygosity, and the economics of producing and evaluating large segregating populations of trees are some of the difficulties encountered in breeding forest trees.

Genetic engineering offers prospects for generating novel forest tree genotypes at an accelerated rate. One major advantage of this approach over conventional breeding is that only the characteristics of interest are inserted into the recipient plant while the original genetic framework remains unchanged. Although genetic engineering in trees is still in its infancy, several studies have clearly established its potential for introducing novel genetic characters, such as herbicide tolerance, insect resistance, or modifying lignin content (Tzfira *et al.*, 1998; Ahuja, 2000; van Frankenhuyzen and Beardmore, 2004).

2. GENETIC TRANSFORMATION

2.1 Organogenesis in Casuarina

The ability to regenerate a plant species following *in vitro* cultivation of a transformed cell remains a critical factor for the success of a genetic transformation procedure. Shoot regeneration from calli has been described for both *C. glauca* and *A. verticillata* (Duhoux *et al.*, 1996).

Epicotyls from 4- to 5-week-old seedlings were cut into 2-cm pieces and cultured on a MSC (Murashige and Skoog medium modified for Casuarina) medium containing half-strength MS salts, Nitsch and Nitsch vitamins, 20 g l⁻¹ sucrose at pH 5.6 and supplemented with 0.5 µM naphthalene acetic acid (NAA), and 2.5 µM benzylaminopurine (BA). After 2 months, callogenesis was observed on 40% of *C. glauca* explants and on 90% of *A. verticillata* epicotyl fragments. Buds elongated into shoots within 6 months on 41% of *C. glauca* calli. Shoots proliferation was observed within 4 months on 85% of *A. verticillata* calli.

When *C. glauca* shoots were about 3 cm in height, they were excised and root formation induced by a 3-day treatment with 10 μ M indole-3-butyric acid (IBA) (Franché *et al.*, 1999). The same procedure was followed for *A. verticillata* using 25 μ M NAA (Franché *et al.*, 1997).

2.2 Antibiotics for the Selection of Transformed Tissue in Casuarinaceae

The sensitivity of Casuarinaceae epicotyls to the antibiotic kanamycin was established before the first gene transfer experiment (Le *et al.*, 1996). Experimental results established that *C. glauca* is more sensitive to antibiotics than *A. verticillata*. Complete inhibition of callus growth on untransformed explants cultivated on a callus-induction medium can be obtained at a kanamycin concentration of 50 mg l⁻¹ for *C. glauca* whereas 100 mg l⁻¹ is necessary for *A. verticillata*. Unpublished data concerning *C. equisetifolia* indicate that selection for transformed cells requires 50 mg l⁻¹ of kanamycin.

Cefotaxime is the antibiotic used to eliminate *Agrobacteria* in plant tissues. In Casuarinaceae, it had no adverse effect on shoot differentiation when used at a concentration ranging from 250 to 500 mg l⁻¹ (Le *et al.*, 1996).

2.3 Gene Transfer Methods

2.3.1 Direct gene transfer based on particle bombardment

Particle bombardment is a valuable technology for transient expression of new gene constructs in target plant cells and can be used to generate transgenic plants in species that are recalcitrant to *Agrobacterium* (Sanford, 2000; Kikkert *et al.*, 2005). This method was tested on cotyledons, epicotyls, and hypocotyls excised from 2-month-old *C. glauca* seedlings (Franché *et al.*, 1999).

A helium particle gun was used to accelerate 1 μ M tungsten beads coated with a plasmid containing the β -glucuronidase gene (*gus*) under the control of the constitutive cauliflower mosaic virus (CaMV) promoter 35S. Bombardment of the cotyledons led to the most efficient and reproducible data for transient expression. An average of three *gus*-expressing units was observed

on the cotyledons 2 days after bombardment. The low efficiency of gene transfer is mainly linked to the small size (about 2 mm) of the cotyledons from *C. glauca*. Stable genetic transformation has never been reported in Casuarinaceae using this approach, and the low frequency of stable transgene integration is a major limitation.

2.3.2 Gene transfer based on *Agrobacterium rhizogenes*

Susceptibility of Casuarinaceae to *Agrobacterium rhizogenes* was demonstrated in 1991 (Phelep *et al.*, 1991). The agropine-type strain A4 (Petit *et al.*, 1983) and the cucumopine-type strain 2659 (Davioud *et al.*, 1988) were found to induce hairy roots on seedlings of *A. verticillata*. This property can be used to produce partially transformed plants (composite plants) of *C. glauca* (Diouf *et al.*, 1995) and fully transformed plants of *A. verticillata* (Phelep *et al.*, 1991).

The rapid procedure for composite *C. glauca* relies on the induction of a hairy root system by *A. rhizogenes* while the aerial part of the plant remains untransformed (Figures 6–7). Young seedlings of *C. glauca* were wounded on the hypocotyl and inoculated with *A. rhizogenes* A4RS containing the binary vector pBIN35S-*gus-int* that carries a derivative of the β -glucuronidase reporter gene *gus-int* expressed only upon transfer to the plant cells and not in *Agrobacterium* (Vancanneyt *et al.*, 1990). After 2 weeks, highly branched roots exhibiting rapid growth were observed at the inoculation site. The normal root system was removed at the stem base, and the composite plant decontaminated with cefotaxime at 300 mg l⁻¹. GUS reporter gene activity was observed in about 50% of *C. glauca* hairy roots, indicating a cotransfer of the genes carried on the T-DNA (transfer-DNA) of the pBIN vector and those of the root inducing (Ri)-plasmid. After inoculation with *Frankia*, nodulation was observed on 40% of the transformed roots. Using this “composite plant” approach, the expression and the function of a chimeric gene can be studied in both roots and nodules of *C. glauca* within 4 months. The same approach can be used on *A. verticillata* (Franché, unpublished data).

Fully transformed plants of *A. verticillata* can be obtained following genetic transformation by

Figure 6 Hairy roots developing on the hypocotyl of *C. glauca* after inoculation by *A. rhizogenes* 2659

the A4 or 2659 strains of *A. rhizogenes* (Phelep *et al.*, 1991). After inoculation with A4, 20% of the epicotyls from 2-month-old seedlings developed hairy roots. After excision, the transformed roots were grown on a MSC medium supplemented with $1.25\ \mu\text{M}$ NAA and $0.5\ \mu\text{M}$ BA. Two months later, shoot regeneration was observed on a few of A4-induced roots. In contrast, shoot regeneration occurs spontaneously on 90% of the *A. rhizogenes* 2659 transformed roots after 3 months of culture on a hormone-free medium. All the shoots developed roots when placed in a nutrient medium with $0.5\ \mu\text{M}$ of IBA. However, the phenotype of the transgenic plants differed from that of the control plants (Figure 8). The transgenic regenerants were characterized by a better developed root system, plagiotropic, and more branched than the normal nontransformed

Figure 7 Composite plant (left) obtained after inoculation by *A. rhizogenes* A4 and control plant (right) of *C. glauca*

roots. The root dry weight of the transformed plant was five times higher than that of the control plants. The aerial system showed reduced apical dominance with highly branched shoots and the dry weight of the transgenic was two times higher than that of the normal regenerant.

2.3.3 Gene transfer based on *Agrobacterium tumefaciens*

The natural susceptibility of members of the Caesariaceae family to *Agrobacterium tumefaciens* was used to develop a gene transfer procedure for both *A. verticillata* (Franchet *et al.*, 1997) and *C. glauca* (Smouni *et al.*, 2002). A number of physiological and environmental factors, such as the presence of plant phenolic compounds (acetosyringone), sugars, pH, temperature, and

Figure 8 Control plant (right) and transgenic plants (middle and left) fully transformed by *A. rhizogenes* A4

osmoprotectant compounds, influence the induction of virulence genes and, consequently, the efficiency of T-DNA transfer from *A. tumefaciens* to the wounded plant cells (Gelvin, 2000). Preliminary experiments performed with *C. glauca* showed that optimal transformation rates are obtained when epicotyls from 45-day-old seedlings are co-cultivated for 3 days at pH 5.6 with the *A. tumefaciens* strain C58C1 (pGV2260) (Le *et al.*, 1996). The efficiency of genetic transformation by the strain LBA4404 (pLBA4404) (Hoekema *et al.*, 1983) is 1.5–2.5 times lower than that obtained with C58C1 (pGV2260) (Vancanneyt *et al.*, 1990).

In the optimal conditions previously described, respectively 26% and 39% of the epicotyls from *C. glauca* and *A. verticillata* that were genetically transformed with the strain C58C1 (pGV2260; pBIN19-35S-*gus-int*) developed one to three calli growing in the presence of kanamycin

Figure 9 Bud differentiation on a transgenic callus of *C. glauca* obtained after genetic transformation by *A. tumefaciens* C58C1 (pGV2260)

(50 mg l⁻¹ for *C. glauca* and 100 mg l⁻¹ for *A. verticillata*) (Figure 9). About 95% of these calli expressed β -glucuronidase reporter gene activity and the integration of the transgenes was further confirmed by polymerase chain reaction (PCR) and Southern blot analyses. Transgenic plants were regenerated in approximately 9–10 months for *C. glauca* and in 4–6 months for *A. verticillata*. The phenotype and the nodulation efficiency conferred by *Frankia* was found to be similar in transgenic Casuarinaceae and in nontransformed control plants (Figure 10), and the transgenic nodules fixed nitrogen at the same rate as those of the nontransformed control nodules.

The transformation procedure developed on *C. glauca* and *A. verticillata* has several major advantages: kanamycin selection is efficient and there are very few escapes; only one medium is required for both bud differentiation and shoot elongation; and it is possible to regenerate numerous trees from a single callus in a reasonable period of time.

2.4 Promoters for the Expression of Valuable Traits in Casuarinaceae

2.4.1 Promoters for constitutive expression

The CaMV 35S promoter (Odell *et al.*, 1988) is the most widely used sequence for constitutive

Figure 10 One-month-old nontransformed plant (left) and transgenic rooted plant (right) obtained after genetic transformation by *A. tumefaciens* C58C1 (pGV2260)

expression of foreign genes in plants. The expression pattern conferred by this sequence has been reported in transgenic 35S-*gus* *C. glauca* (Smouni *et al.*, 2000, 2002) and *A. verticillata* plants grown either *in vitro* for 2 months or for 1 year in a glasshouse (Obertello *et al.*, 2005).

In 2-month-old transgenic *C. glauca* plants, 35S was expressed constitutively in the shoots, and reporter gene activity generally increased with distance from the shoot apex (Smouni *et al.*, 2002). In the primary root, activity was detected throughout the main root except in the elongation zone. Observations on main root transverse sections showed intense blue staining in the vascular system, including the xylem, phloem tissues, and pericycle. The large, thin-walled cells of the cortex and rhizoderm were lightly stained. As noted in the aerial parts of the plant, the intensity of staining increased with root diameter and distance from the root tip. In emerging lateral roots, promoter activity was restricted to the root cap. In older lateral roots,

blue staining was also visible in the proximal region of the vascular tissue (Smouni *et al.*, 2002). In actinorhizal nodules, intense GUS activity was seen in the vascular bundle, the phellogen, and in strands of uninfected cells filled with polyphenols. 35S-*gus* expression was undetectable in *Frankia*-infected cells. Analysis of 35S-*gus* *C. glauca* grown for 1 year in a glasshouse revealed a nearly constitutive pattern of expression (Smouni *et al.*, 2002). The *CaMV* promoter was highly active in both roots and shoots, except in peripheral suberized tissues. These data were confirmed by detailed fluorometric analysis of a transgenic 35S-*gus* *C. glauca* tree (Smouni *et al.*, 2000).

In the search for promoters that drive strong constitutive expression in *A. verticillata*, the specificity of *gus* expression conferred by four different promoters has been compared (Obertello *et al.*, 2005). The sequences studied include the 35S promoter, the enhanced double 35S (*e35S*) (Kay *et al.*, 1987), the *e35S-5ocs* that contains four copies of the *ocs* (octopine synthase) element (Ellis *et al.*, 1987), and the ubiquitin 1 (*UBQ1*) promoter from *Arabidopsis thaliana* (Callis *et al.*, 1990). The 35S promoter was constitutively expressed except in the shoot apex and in lateral roots. The *e35S* and *e35S-4ocs* drove high constitutive expression in non-nodulated *A. verticillata*. In contrast, the *UBQ1* promoter that is nearly constitutive in *Arabidopsis* was poorly expressed in *Casuarina*. None of the four promoters drove expression in the *Frankia*-infected cells of actinorhizal nodules.

2.4.2 Promoters for root- or nodule-specific expression

Promoters tested for root- and nodule-specific expression include *cgMT1*, a sequence from a metallothionein (MT) gene from *C. glauca* (Laplaze *et al.*, 2002), and two heterologous promoters from hemoglobin genes (Franche *et al.*, 1998a).

PcgMT1 is a 1.2-kb fragment corresponding to the promoter region of a type 1-MT gene isolated from a nodule complementary DNA (library of *C. glauca* (Laplaze *et al.*, 2002). In transgenic *A. verticillata* plants, *PcgMT1* drives a constitutive *gus* expression in lateral roots whereas the aerial part did not express the reporter gene except in the oldest shoot

region. In transgenic nodules of *A. verticillata*, β -glucuronidase expression was restricted to large *Frankia*-infected cells. No activity was observed in noninfected cells of the cortex, in the periderm, vascular bundle, or meristematic zone. Induction experiments performed on whole plants revealed that *PcgMTI* responds to wounding, oxidative stress, and pathogen infection. Thus, this promoter appears to be a valuable sequence to drive expression in roots, in *Frankia*-infected cells, and in plants under oxidative stress.

Symbiotic hemoglobin is a protein present at high concentrations in the nitrogen-fixing nodules of both legumes and nonlegumes, where it facilitates oxygen diffusion to nitrogen-fixing endosymbiotic bacteria (Appleby, 1992). Two different hemoglobin promoters were studied in transgenic Casuarinaceae: the promoter region of the hemoglobin gene from soybean (*lbc3*) (Lauridsen *et al.*, 1993) and from *Parasponia andersonii* (Bogusz *et al.*, 1988). *lbc3* is a symbiotic gene expressed at high levels in soybean nodules (Lauridsen *et al.*, 1993). *P. andersonii*, a nonlegume belonging to the family Ulmaceae, lives in symbiotic association with *Rhizobium* (Trinick, 1979); the *Parasponia* hemoglobin sequence is expressed both in the nitrogen-fixing nodules and at low levels in the root tissue (Bogusz *et al.*, 1988). In transgenic *C. glauca* and *A. verticillata*, the soybean and *P. andersonii* hemoglobin promoters direct expression of the *gus* gene in *Frankia*-infected cells; some blue staining was also observed in the root tip of the *Parasponia* construct (Franché *et al.*, 1998a). No expression was observed in the aerial parts of the transgenic plants. So far, these two hemoglobin promoters are considered to be the best sequences to drive a high level of transgene expression in *Frankia*-infected cells.

2.5 *gus* and *gfp* as Reporter Genes in Transgenic Casuarinaceae

Reporter genes have been used as convenient markers to visualize gene expression and protein localization *in vivo* in a wide spectrum of procaryotes and eucaryotes. A comparison of the *gus* and *gfp* (green fluorescent protein) reporter genes was undertaken to determine which marker is the most suitable for gene expression studies in transgenic Casuarinaceae (Santi *et al.*, 2003).

The β -glucuronidase assay invented by Jefferson is very sensitive, and it is possible to obtain both qualitative (histochemical) and quantitative (fluorometric) data (Jefferson *et al.*, 1987). As previously mentioned in this chapter, the first genetic transformation experiments of Casuarinaceae proceeded through the use of the *gus* reporter gene (Franché *et al.*, 1997). Histochemical assays established that the chromogenic substrate 5-bromo-4-chloro-3-indolyl- β -D-glucuronide (X-gluc) can easily penetrate calli, shoots, and roots, but does not penetrate directly in nodules. Reporter gene activity can only be observed in 45- μ m-thick nodule sections obtained on a vibratome. This treatment is absolutely necessary to compensate for the poor penetration of the GUS substrate in nodules of transgenic Casuarinaceae.

One major problem that is sometimes encountered in fluorometric β -glucuronidase analyses performed on woody plants is linked to the presence of phenolic compounds, which can interfere with GUS activity (Jefferson *et al.*, 1987). This inhibition has been observed in protein extracts of Casuarinaceae, mainly in nodules and to a lesser extent in roots. Adding polyvinylpyrrolidone (PVPP) during preparation of protein extracts can overcome the problem. With the addition of insoluble PVPP (0.5 g g⁻¹ fresh weight tissue) to the protein extraction buffer, GUS activities measured in actinorhizal nodules and roots increased by a factor of 70 and 9.8, respectively. It has been suggested that PVPP can specifically absorb phenolic compounds that act as inhibitors of GUS enzymatic activity (Serres *et al.*, 1997).

Because the GUS assay is toxic and destructive, it cannot be used to monitor gene expression *in vivo*. This is a major obstacle for kinetic analyses of symbiotic gene expression during differentiation of actinorhizal nodules. The GFP from the jellyfish *Aequorea victoria*, which emits bright fluorescence upon excitation with ultraviolet or blue light GFP, thus appears to provide a useful alternative to GUS (Chalfie *et al.*, 1994). Analysis of transgenic *35S-mgfp5-ER* (Haseloff *et al.*, 1997) *A. verticillata* plants revealed clearly visible fluorescence in the transformed root system (Santi *et al.*, 2003). In shoots, fluorescence was only detected in the young scales of the apex but it was masked by chlorophyll in other parts of the shoots. Under UV light, prenodules and nodules exhibited strong green GFP fluorescence making them easy to

identify in the lignified root system. However, in control nodules obtained after inoculation of nontransformed *A. verticillata* plants, a low level of green autofluorescence was observed. This level of autofluorescence of the nodule makes analysis of weak promoters difficult for gene expression studies in transgenic Casuarinaceae. Their study thus requires the use of more sophisticated methods such as confocal microscopy.

3. FUTURE ROAD MAP

3.1 Transgenic Casuarinaceae as a Tool for Functional Genomics in Actinorhizal Plants

In the past decade, some progress has been made in the knowledge of the plant genes that are expressed at different stages of Casuarina nodule differentiation, and genomic approaches have been initiated (Franché *et al.*, 1998b; Obertello *et al.*, 2003; Hoche *et al.*, 2006). The genetic transformation procedures developed in the Casuarinaceae family now make it possible to perform functional analysis of plant symbiotic genes. These approaches include promoter studies, over- and underexpression of plant genes using sense and antisense constructs, and RNA interference. Promoter-reporter gene fusions have already been shown to be particularly appropriate in Casuarina when the expression of the symbiotic genes is limited to discrete subpopulations of cells within a given organ such as a root or a nodule (Laplaze *et al.*, 2002; Santi *et al.*, 2003; Svistoonoff *et al.*, 2003).

3.2 Transgenic Casuarinaceae as a Tool for Evolutionary Studies of N₂ Fixing Symbioses

The symbiotic association between *Frankia* and Casuarina exhibits striking differences to the *Rhizobium*-legume symbiosis (Pawlowski and Bisseling, 1996; Wall, 2000; Vessey *et al.*, 2005). *Frankia* is a filamentous, branching, gram-positive actinomycete, whereas *Rhizobia* are gram-negative unicellular bacteria. Legume root nodules are stemlike structures with peripheral vascular bundles and infected cells in the central

tissue, whereas actinorhizal nodules conserve the structure of a lateral root with a central vascular bundle and peripheral infected cortical tissue. Nevertheless, recent phylogenetic data showed that all nodule-forming plants belong to a single clade suggesting a single origin of the predisposition for nitrogen fixation in the angiosperms (Soltis *et al.*, 1995).

Transgenic Casuarinaceae trees provide valuable tools to investigate the conservation of the mechanisms for nodule-specific expression between legumes and actinorhizal plants. Using transgenic Casuarina expressing *gus* driven by promoters from nodulin genes of legumes, transgene expression during ontogenesis of the actinorhizal nodules can be investigated and the data compared to those reported in legumes. This approach has already been used for a number of symbiotic promoters from both early nodulin genes such as *enod40* (Santi *et al.*, 2002) and *enod 12* (Sy *et al.*, 2006), and from late nodulin hemoglobin genes (Franché *et al.*, 1998a). A deeper understanding of the different types of nitrogen-fixing nodules will facilitate the development of future strategies to modify lateral root development on nonsymbiotic plants to enable some to associate with nitrogen-fixing bacteria.

3.3 Gene Transfer for the Improvement of Casuarinaceae

Gene transfer procedures based on *A. tumefaciens* and knowledge of gene expression conferred by heterologous promoters such as the 35S in Casuarinaceae pave the way for genetic engineering of these tropical trees. Furthermore, the isolation and characterization of promoters from Casuarina will contribute to providing sequences that are well suited for the expression of valuable traits in these tropical trees.

Strategies can be developed to engineer Casuarina to resist major pathogens, such as *Rhizoctonia solani*, and insect pests, such as *L. xyli*. Transgenic trees that are more tolerant to adverse edaphic conditions, such as salt and drought, would also be very valuable in tropical regions. Other aspects may include modification of lignin content and/or composition to obtain trees that are more suitable for industrial uses.

Paper production has more than tripled in the last 35 years and the paper industry suffers from the high cost of removing lignin from cellulose, which also has a negative environmental impact (Jouanin and Goujon, 2004). Another goal linked to lignin modification could be to prevent *Casuarina* wood from splitting when it dries. This is currently a major drawback for the use of *Casuarina* wood for the manufacture of furniture.

At the time of writing, no transgenic *Casuarina* trees have yet been planted in the field. Additional information on the stability of transgene expression in field-grown Casuarinaceae exposed to changing environments is thus needed to determine the real potential of genetic engineering for the introduction of valuable new traits in this tropical tree family. Furthermore, to prevent an uncontrolled escape into the environment, efforts should be made to obtain sterile transgenic Casuarinaceae trees that do not form fertile pollen or seeds.

1. INTRODUCTION

1.1 History, Origin, and Distribution

Robinia pseudoacacia L. (black locust, false acacia, robinia, honey locust, pea flower, post locust, yellow locust, green locust, and white locust) is a nitrogen-fixing deciduous tree native to eastern North America from the Ozark–Ouachita region to the southern Appalachians. It is widely cultivated as an ornamental tree in many parts of the world (Figures 1a and b). The genus *Robinia* is dedicated to Jean Robin (1550–1629) and his son Vespasian Robin (1579–1662), herbalists to the kings of France and the first to cultivate black locust in Europe at the beginning of the 17th century. The specific name of *pseudoacacia* comes from its obvious similarity to the subtropical acacias of Africa. Since its discovery, the tree has become widely distributed not only in Europe but also throughout the temperate and Mediterranean zones of the world. Because it is a nitrogen fixer and has rapid juvenile growth, it is widely planted as an ornamental, for shelterbelts, and for land reclamation. It is suitable for fuel wood and pulp, and provides cover for wildlife, browse for deer, and nesting cavities for birds. *Robinia* is the second most widely planted hardwood genus in the world (Keresztesi, 1980). The species has escaped cultivation and become naturalized throughout the United States, southern Canada, and parts of Europe and Asia.

1.2 Botanical Description

Black locust belongs to Division Magnoliophyta, Class Magnoliopsida, Order Fabales, Family Fabaceae, Genus *Robinia*, and species *pseudoacacia*. The species is described as a medium-sized tree, generally 12–18 m in height and 30–76 cm in diameter. On better sites it may reach 30 m in height and 122 cm or more in diameter. The leaves are alternate and compound, 15–30 cm long with 7–19 elliptical leaflets, folding at night. The flowers, numerous in drooping racemes 10–20 cm long at the base of leaves, are fragrant and white, about 2 cm long. Blooming in late spring, they are pollinated by honeybees and other insects. The fruit of black locust is a legume 5–10 cm long and 2–3 cm wide, containing four to eight seeds. The fruit ripen during September and October, opening on the tree, and seeds are dispersed from September to April (Olson, 1974). Dry seeds can be stored and they retain their viability for as long as 10 years, if placed in closed containers at 0–5 °C. Young trees grow very fast on good sites, but the species matures early and the growth rate decreases rapidly after 30 years, especially on poor sites. Black locust also produces stump sprouts and root suckers prolifically. In some areas, natural reproduction by root suckers exceeds that by seeds (Huntley, 1990).

The native range of black locust is classified as humid, with two local areas of superhumid climate (Thornwaite, 1931), but black locust seems to do

Figure 1 (a) Adult black locust (*R. pseudoacacia* L.) tree [Reproduced from <http://www.forestryimages.org> with permission of Chris Evans, University of Georgia]; (b) diagram of black locust flowers, leaves, and fruits [Reproduced from <http://www.forestryimages.org> with permission of Zelimir Borzan, retired from the University of Zagreb]

well in many different habitats. The range includes the cool temperate moist forest, warm temperate montane moist forest, warm temperate montane wet forest, and warm temperate moist forest life zones (Sawyer and Lindsey, 1964).

Black locust grows below 1000 m altitude over a wide range of soils with the exception of extremely dry or clayey ones (De Gómez and Wagner, 2001). The most common orders of soil within its native range are Inceptisols, Ultisols, and Alfisols, and the most common soil great groups are Hapludults, Paleudults, Dystrochrepts, and Eutrochrepts (Soil Conservation Service, 1970). The species is intolerant to shade and unless it is a dominant tree, will not grow in dense woods (Trimble, 1975).

In its native area, black locust is severely damaged by coleopteran insects such as *Megacyllene robiniae* Foster (the locust borer, Figure 2) and *Odontota dorsalis* Thunberg (the locust leaf miner), preventing growth of the tree for timber production (Hoffard, 1992). In Hungary, where these pests are not found, it is utilized

as a multipurpose tree (Keresztesi, 1988). In other countries, except for reclamation, most forest managers consider the tree to be a weed species and a strong competitor against more desirable species (Hanover, 1993). Recent

Figure 2 Wood damage caused by locust borer (*M. robiniae* Forster) [Reproduced from <http://www.forestryimages.org> with permission of James Solomon, USDA Forest Service]

studies identified several allelopathic substances including robinetin, myricetin, and quercetin from leaf tissues, suggesting a potential role of these flavonoids in *R. pseudoacacia* invasion in introduced habitats (Nasir *et al.*, 2005).

Black locust has a small genome size ($1C = 0.65$ pg, picogram) (Bennett and Leitch, 2005) and is primarily diploid ($2n = 20$), although it can occur as a polyploid. In fact, a tetraploid clone has been described in Korea (Kim and Lee, 1973). Several cultural varieties have been recognized in the United States (Bongarten, 1992; Hanover, 1993) and Europe (Keresztesi, 1988). Shipmast locust (*R. pseudoacacia* var. *rectissima*), a clone of unknown origin, is listed by Little (1979) as a natural variety. Surles *et al.* (1989) reported a high degree of polymorphism (71%) for 18 enzyme systems in the species. Four hybrids resulting from crosses with Kelsey locust, *Robinia kelseyi* Hutch. (*R. × slavinii* Rehd.); New Mexico locust, *Robinia neomexicana* Gray (*R. × holtii* Beissn.); clammy locust, *Robinia viscosa* Vent. (*R. × ambigua* Poir.); and bristly locust, *Robinia hispida* L. (*R. × margaretta* Ashe) are recognized (Little, 1979).

Black locust contributes high levels of nitrogen to the soil from nitrogen-fixing bacterial symbiosis (De Gómez and Wagner, 2001). Studies on rhizobial strains nodulating black locust demonstrated that the species is nodulated with a high diversity of rhizobial strains, most of which belong to the genus *Mesorhizobium*. This rhizobial diversity may contribute to the success of black locust as a pioneer tree species in the temperate zone (Ulrich and Zaspel, 2000).

1.3 Economic Importance

Black locust is widely planted in the United States, Europe, and Asia for erosion control, reclamation of drastically disturbed sites, windbreaks, nurse crops, amelioration of sites, honey production, and ornamental use. It is also suitable for use in fuel plantations (Eigel *et al.*, 1980; Geyer and Naughton, 1980).

Black locust wood is very heavy and hard, exceedingly strong and stiff, and has very high shock resistance and high nail-holding qualities. The heartwood has high decay resistance due to flavonoids and can endure for over 100 years in the

soil (Barrett *et al.*, 1990; Hizioglu and Kamdem, 1995). Because of its durability, the primary use of black locust wood has been for fence posts, mine timbers, poles, railroad ties, insulator pins, ship timber, tree nails for wooden ship construction, boxes, crates, pegs, stakes, and novelties. However, in the United States, severe damage by the locust borer mentioned earlier, as well as the fungi (*Phellinus rimosus* and *Polyporus robiniophilus*) that attack the stem, causing deformation or breakage, has virtually removed the species from lumber production (Hanover, 1993). In Hungary, where the insect is not a problem, black locust is a major timber tree (Keresztesi, 1988). The wood is also suitable for chemical pulping systems in the paper industry (Miller *et al.*, 1987; Hanover and Mebrahtu, 1991).

Black locust's virtues, including nitrogen-fixing ability, inexpensive propagation by seed, rapid vegetative propagation, adaptability to a wide range of site conditions, rapid juvenile growth, high heat content of the wood, and prolific regrowth after cutting, make the species widely used for erosion control, reforestation, and woody biomass plantings. Commercial energy production may eventually become one of its primary uses in the United States (Miller *et al.*, 1987).

Black locust is valued for its beneficial effect on neighboring trees in the form of nitrogen-fixing activity around the roots and in elements released from decomposing litter (Landgraf *et al.*, 2005). It is an outstanding tree for reclamation (Kim and Lee, 2005) and phytostabilization of unsanitary landfills (Mertens *et al.*, 2004). Planting the species on mine sites provides the advantages of watershed protection, site amelioration, aesthetic enhancement, screening, and food and habitat for wildlife. Leaves of the species have also been used to monitor heavy metal contamination in soils (Celik *et al.*, 2005).

In Hungary, black locust plantings are vital to commercial honey production (Keresztesi, 1988). The leaves are used for livestock feed (forage) in the Republic of Korea and in Bulgaria (Keresztesi, 1983, 1988). For this purpose, in the highlands of Nepal and northern India, where black locust is naturalized, a tetraploid black locust clone, *R. pseudoacacia* "Gigas", with leaves three times larger than other genotypes and with higher protein content, is used (Baertsche *et al.*, 1986).

1.4 Traditional Breeding: Breeding Objectives, Tools and Strategies, and Achievements

Because black locust has been widely planted, the proper seed treatment and nursery practices are well described. Black locust produces abundant seeds, but the seeds remain dormant. Seed coats are impermeable and germination must be induced by scarification. Soaking in concentrated sulfuric acid, soaking in boiling or near-boiling water, and mechanical scarification have proven successful to induce germination (Hartmann *et al.*, 1997). The species can also be propagated by root cuttings and by grafting using a whip, side veneer, cleft, or wedge graft (Parr, 1983; Ward, 1993), but success rates vary among clones. Grafted or rooted shoot sections produce lateral growth, while sprouts from roots grow upright (Prentice, 1987). Sprouts grow more rapidly than seedlings.

The first breeding work began in Hungary in 1930, and many improved cultivars for specific uses such as wood and nectar production have been registered (Keresztesi, 1983). Clonal selection, early pruning, and close spacing have been effective means to produce straight-stemmed black locust plantations. Breeding programs have been developed in the United States for biomass production (Miller *et al.*, 1987; Barrett *et al.*, 1990; Bongarten *et al.*, 1992) and for other traits such as growth rate, borer resistance, or stem form (Hanover, 1993). These programs were carried out at the Michigan State University and the University of Georgia (Kennedy, 1983; Miller *et al.*, 1987). All traits showed family differences, but no variation by region of origin was found (Mebrahtu and Hanover, 1989). Superior individuals have been reproduced from stem and root cuttings, and established in plots of single clones to be used for seed production and forage/biomass studies. Selection and propagation of trees with superior vigor, form, and resistance to borers have been attempted.

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

Traditional breeding efforts have been so far inefficient, mainly due to the difficulty in obtaining controlled crosses (Han *et al.*, 1999), making it

difficult to fix desirable alleles in a particular highly heterozygous background (Williams and Savolainen, 1996). Thus, conventional breeding is rather slow and unproductive and cannot be used efficiently for the genetic improvement of trees. In black locust, selection and propagation of trees with superior vigor, form, and resistance to borers have been attempted using traditional vegetative propagation methods. Early results indicate significant differences in borer attack among clones and sites; however, differences were small and to date have had no practical application.

Plant tissue culture and genetic transformation methods offer an important option for the effective multiplication and improvement of trees within a limited time frame (Giri *et al.*, 2004). Genetic engineering assumes additional significance because of the possibility of introducing a desired gene in a single step for precision breeding of forest trees. Genetic transformation requires the development of methods for *in vitro* regeneration of the species. Three black locust *in vitro* regeneration pathways have been reported: axillary bud elongation and multiplication from nodal or apical buds (Chalupa, 1983, 1987; Barghchi, 1987; Davis and Keathley, 1987; Han *et al.*, 1997); differentiation of adventitious buds from various plant organs (Brown and Sommer, 1982; Davis and Keathley, 1985; Han and Keathley, 1989; Arrillaga and Merkle, 1993; Han *et al.*, 1997); and somatic embryogenesis from immature embryos (Merkle and Wiecko, 1989; Arrillaga *et al.*, 1994) (Figure 3). These techniques will allow mass propagation and/or conservation of the selected genotypes

Figure 3 Somatic embryos from immature black locust seeds

(Verleysen *et al.*, 2005) and are the basis for the application of transgenic technology that will produce trees with superior qualities such as disease and pest resistance and high wood quality.

2. REVIEW ON TRANSGENICS DEVELOPED

In spite of its feasibility to be propagated by *in vitro* techniques, there are a few reports on successful protocols to regenerate normal transgenic black locust plants. The latest review on this subject (Han *et al.*, 1999) reported the susceptibility of black locust to *Agrobacterium* infection (Davis and Keathley, 1989) and the production of transgenic plants after co-culture with either *Agrobacterium rhizogenes* (Han *et al.*, 1993) or *Agrobacterium tumefaciens* (Ahn, 1995).

Briefly, Davis and Keathley (1989) inoculated cotyledons and hypocotyls with five *A. tumefaciens* strains and one *A. rhizogenes* strain. Infection with wildtype A6, A348, A247, and A208 *A. tumefaciens* strains incited unorganized tumors, whereas wild A4 *A. rhizogenes* strain induced hairy roots. A modified A281 *A. tumefaciens* strain carrying the binary vector pGA472 with the neomycin phosphotransferase (*nptII*) gene produced kanamycin-resistant callus (Davis and Keathley, 1989). In all cases, Southern hybridiza-

tion indicated that transfer-DNA (T-DNA) was integrated into the DNA of tumors or calli. Han *et al.* (1993) obtained hairy roots after inoculating hypocotyl explants with *A. rhizogenes* R1601 strain carrying the *nptII* gene. Subsequently, hairy roots were isolated and cultured in the presence of kanamycin to induce callus and further shoot regeneration. The integration of the transgene in the regenerated plants was confirmed by Southern hybridization. Nevertheless, only abnormal plants with dark green and wrinkled leaves and hairy root phenotypes were obtained (Han *et al.*, 1993). Finally, the review reported on the production of transgenic black locust shoots following inoculation of hypocotyls with *A. tumefaciens* LBA4404 strain carrying the binary vector pBSW1. Integration of transgenes was confirmed by Southern hybridization (Ahn, 1995).

Recent results describing procedures to obtain transgenic black locust plants are summarized in Table 1 and discussed in the following sections.

2.1 Plant Material and Culture Media

To the best of our knowledge, the explant sources used for genetic transformation of black locust are as follows: (1) an embryogenic culture line (BL2-1C) initiated from immature embryos as described by Merkle and Wiecko (1989) and

Table 1 Black locust transformation protocols based on *Agrobacterium tumefaciens* infection

maintained as a suspension of proembryogenic masses (PEMs); (2) hypocotyls from 15-day-old seedlings germinated on sterilized sand (Kanwar *et al.*, 2003); (3) cotyledons from freshly isolated embryos (Zaragoza *et al.*, 2004); and (4) leaf or stem segments from *in vitro* grown plants (Igasaki *et al.*, 2000).

Culture media consisted of Murashige and Skoog (MS) (Murashige and Skoog, 1962) macronutrients and micronutrients salts, MS or B5 vitamins (Gamborg *et al.*, 1968), and different combinations of plant growth regulators (auxins and cytokinins). In the case of the embryogenic culture used for transformation, PEMs were maintained on a modified 10A40N medium (Finer and Nagasawa, 1988) supplemented with 8.8 μM 2,4-dichlorophenoxyacetic acid (2,4-D)

(here designated FM, Finer's medium). Media composition, antibiotics, and selective agents are described in Table 2.

2.2 Selection of Transformed Tissue

Before attempting transformation, sensitivity of the target material to several selective agents (antibiotics such as kanamycin, geneticin, and hygromycin, and herbicides such as phosphinothricin) was tested (see Table 3). Explant performance was recorded after 3–4 weeks. Hypocotyl and leaf explants were cultured on a kanamycin-containing medium. For hypocotyls, 0, 10, 20, 30, and 40 mg l⁻¹ kanamycin were used (Kanwar *et al.*, 2003), whereas 25, 50, 100, and

Table 3 Selective agents and concentrations tested for genetic transformation in black locust

Tissue	Genes	Selective agent	Range tested (mg l ⁻¹)	Optimal concentration	References
PEMs	<i>nptII</i>	Kanamycin	0–200	None	Arrillaga and Merkle, 1994
		Geneticin	0–50	10 mg l ⁻¹	
Hypocotyl	<i>nptII</i>	Kanamycin	0–40	50 mg l ⁻¹	Kanwar <i>et al.</i> , 2003
Leaf	<i>nptII</i>	Kanamycin	0–200	None	Igasaki <i>et al.</i> , 2000
	<i>hpt</i>	Hygromycin	0–40	20 mg l ⁻¹	Igasaki <i>et al.</i> , 2000
Cotyledon	<i>bar</i>	Phosphinothricin	0–15	4 mg l ⁻¹	Zaragoza <i>et al.</i> , 2004

200 mg l⁻¹ were tested for leaves (Igasaki *et al.*, 2000). The kanamycin sensitivity test performed by Kanwar *et al.* (2003) revealed that callus from hypocotyl explants was inhibited in the presence of 10 mg l⁻¹ kanamycin, but these authors used a higher kanamycin concentration (50 mg l⁻¹) for transformation experiments (Kanwar *et al.*, 2003). In contrast, Igasaki *et al.* (2000) found that this antibiotic did not inhibit callus growth in nontransgenic tissue, even when used at concentrations of 200 mg l⁻¹. Therefore, they tested the effect of hygromycin B at 0, 5, 10, 20, and 40 mg l⁻¹ on leaf explants. The results suggested that the *hpt* (hygromycin phosphotransferase) gene was most suitable as a selectable marker gene, since 20 mg l⁻¹ hygromycin B inhibited growth. This level was used in subsequent transformation experiments. Tolerance of cotyledon explants to phosphinothricin (PPT) at 0, 5, 10, and 15 mg l⁻¹ was tested. The presence of 5 mg l⁻¹ PPT inhibited organogenesis. Therefore, for selection of putative transgenic black locust shoots, 4 mg l⁻¹ PPT were added to the culture medium (Zaragoza *et al.*, 2004). In PEMs, the capability of kanamycin (25, 50, 75, 100, 150, and 200 mg l⁻¹) and geneticin (0, 5, 10, 15, 20, and 25 mg l⁻¹) to inhibit growth of nontransformed black locust PEMs demonstrated that kanamycin was not as effective a selection agent as geneticin. Even at 200 mg l⁻¹, kanamycin failed to inhibit growth, whereas a severe growth inhibition was observed at concentrations of geneticin higher than 10 mg l⁻¹ (Arrillaga and Merkle, 1994).

2.3 Direct DNA Transfer

Arrillaga and Merkle (1994) used the biolistic approach in an attempt to transform black locust PEMs. First, factors affecting DNA delivery, such as gas pressure propelling the macrocarrier and gap distance between the rupture disk and the macrocarrier, were tested. The best results in terms of transient β -glucuronidase (GUS) expression were obtained with a rupture disc that broke at 1100 psi (7.5 MPa) and a gap distance of 6.5 mm. In these experiments, plasmid pBI121, containing the selectable marker gene *nptII* driven by the nopaline synthase promoter (NOS), and the reporter gene *gusA* fused to the

cauliflower mosaic virus (CaMV) 35S promoter was used. Subsequently, PEMs were bombarded with plasmid (pBI2S21) where the *gusA* gene was fused to the promoter from a constitutively expressed *Arabidopsis* actin gene, *Ac2*. GUS transient expression assayed 2 days following bombardment and measured as the number of blue spots per plate, increased up to sixfold (900 spots/plate) when the *Ac2* promoter was used (Figure 4). Although some PEMs grew on a selection medium containing 10 mg l⁻¹ geneticin (Figure 5), no stable integration of either transgene was detected by polymerase chain reaction (PCR) or enzyme-linked immunosorbent assay. Therefore, attempts to regenerate somatic embryos from the geneticin-resistant material were discontinued.

Figure 4 Transient GUS expression in black locust proembryonic masses after particle bombardment

Figure 5 Putative black locust transgenic PEMs growing on geneticin containing medium (see arrow)

2.4 *Agrobacterium*-mediated Transformation

2.4.1 Bacterial strains and plasmids

Several disarmed *A. tumefaciens* strains have been used to transfer T-DNA to black locust: LBA4404 (Hoekema *et al.*, 1983), EHA101 (Hood *et al.*, 1986), GV3101 (Koncz and Shell, 1986), and AGL1 (Lazo *et al.*, 1991). These strains harbored the following binary vectors (see Table 3): pBI121 (containing the *gusA* and *nptII* genes both under the control of CaMV 35S promoter); pSMAH704 contained genes for GUS and HPT (Igasaki *et al.*, 2000), and pTAB16 that includes the *bar* (bialaphos resistance) gene, which confers tolerance to the herbicide PPT and the *gusA* gene, both driven by CaMV 35S promoter (Schröder

et al., 1993). The *gusA* gene in pTAB16 plasmid is not expressed in bacteria due to the insertion of a plant intron in the coding region.

2.4.2 Transformation procedures

The published transformation protocols employ different explants, bacterial strains, and plasmids. Because of this variation, procedures are detailed separately. In all cases, *Agrobacterium* was grown overnight and diluted to the appropriate concentration ($1\text{--}5 \times 10^8$ cells/ml) before being used for infection.

Leaf and stem explants (Igasaki *et al.*, 2000). Leaf and stem explants were vacuum infiltrated for 20 min with the bacteria suspension containing 20 μM acetosyringone, then blotted with sterile filter paper and incubated for 2 days. After removing bacteria with several washes on the medium containing carbenicillin and cefotaxime, explants were transferred to the selection medium (Table 2). Regenerated shoots were subcultured to the same medium without growth regulators.

Hypocotyl explants (Kanwar *et al.*, 2003). Prior to infection, explants were preconditioned for 0, 24, 48, or 72 h on a regeneration medium without antibiotics. After infection by immersion 8–10 s in the bacterial suspension, hypocotyls were blotted dry and transferred to the selection medium (Table 2). Calli growing on the selection medium were transferred to the selective MS shoot-induction medium with 0.5 μM NAA (α -naphthaleneacetic acid), 1 μM BA (benzyladenine) and 50 mg l^{-1} kanamycin.

Cotyledon explants (Zaragoza *et al.*, 2004). Freshly isolated cotyledons were preconditioned for 72 h on a regeneration medium with 100 μM acetosyringone. Explants were either incubated or sonicated for 20 min in different bacteria concentrations (optical density 0.3, 0.6, 0.8). Transient GUS expression (see below) was used to determine the best bacterial delivery treatment 3 days after infection. Further experiments included preconditioning of the explants (0, 72, or 96 h) and the period of time before applying herbicide to the culture medium (0 or 3 days). After 3 days of co-culture, explants were transferred to the selection

medium (Table 2). Regenerating explants were transferred to the same medium with 4.4 μM BA and 0.5 μM IAA (indole-3-acetic acid), PPT, and timentin (see Table 2).

2.4.3 Testing transgene activity

Histochemical GUS assay. Histochemical GUS assays (X-gluc) were carried out according to Jefferson *et al.* (1987) and were used for transient expression experiments (Zaragozá *et al.*, 2004) and to detect stable integration in hypocotyl-derived callus, cotyledons, and leaves. Cells and tissues were fixed in 0.3% formaldehyde and 0.3 M mannitol prior to the GUS assay. For fluorimetric assay of GUS activity, 4 mM 4-methylumbelliferyl- β -D-glucuronide (MUG) was used as substrate (Igasaki *et al.*, 2000).

Molecular analysis of the regenerated plants. Genomic DNA was extracted using the Doyle and Doyle (1990) or Murray and Thompson (1980) protocols. Molecular analyses were performed on putative transgenic and control plants by PCR and Southern hybridization. DNA was digested with *Eco*R1, *Bam*H1, and *Hind*III to excise the *bar*, *hpt*, and *gusA* genes, respectively. Filters were hybridized with PCR-labeled *bar*, *hpt*, or *gusA* probes. The presence of introduced DNA was determined by nonradioactive digoxigenin (Zaragozá *et al.*, 2004) or by radioactive (Igasaki *et al.*, 2000) methods.

Chlorophenol red assay (Zaragozá *et al.*, 2004). To test the ability of transgenic plants to detoxify PPT and avoid ammonium accumulation, the chlorophenol red (CR) assay as described by Kramer *et al.* (1993) was used. Putatively transgenic shoots (4 cm length) and controls, previously micropropagated through axillary bud proliferation on the Schenk and Hildebrandt (SH) (Schenk and Hildebrandt, 1972) medium, were cultured in test tubes containing SH with 2 mg l^{-1} PPT and 50 mg l^{-1} CR, gelled with 0.7% agar. The pH of the medium was adjusted to 6.0, a pH at which the medium is a deep red color. The change of color to yellow, indicating that ammonium was not accumulated, was evaluated after 3 days.

Herbicide application. Regenerated plants were acclimatized and tested for their response to herbicide by a leaf spray assay. Transgenic and control plants were sprayed with an aqueous solution containing 160 mg l^{-1} of glufosinate ammonium and 0.1% Tween 20. Results were scored after 4 days.

2.4.4 Regeneration of whole transgenic plants

The three protocols reviewed here are all suitable to produce black locust transgenic plants. Nevertheless the results obtained indicated that the following factors affect transformation efficiency.

Bacterial strain and explant. In a pioneering work, Davis and Keathley (1989) demonstrated that black locust can be infected by a wide range of *Agrobacterium* wild strains. More recently, transgenic plants were obtained after infection with LBA4404, EHA101, GV3101, and AGL1 strains. A general conclusion regarding the best strain for black locust transformation is not feasible since the bacteria carried different plasmids and were used to infect a variety of explants. However, when three different *A. tumefaciens* strains carrying the same plasmid were tested to infect leaf and stem explants, the GV3101 strain led to a transformation frequency higher than that obtained with EHA101 and LBA4404 (Igasaki *et al.*, 2000). The authors also identified stems as the best tissue for such transformation. Arrillaga and Zaragozá (1999) also found that LBA4404 was less effective than EHA105 and AGL1 for infection of black locust cotyledons.

Bacterial delivery. Sonication and vacuum infiltration have been successfully used for bacteria delivery to cotyledons and leaf or stem explants, respectively. Assays of transient GUS expression in control and sonicated cotyledons demonstrated that 1 min of sonication significantly enhanced the percentage of cotyledons with GUS activity (96.7 vs. 75.3 %) as well as the number of blue spots ≥ 1 mm (Figure 6).

Preconditioning of explants. Preculture of explants on a regeneration medium 2–4 days prior to

Figure 6 Transient GUS expression on cotyledon explants 3 days after sonication in a bacterial suspension

transformation was required to obtain transgenic plants from black locust cotyledons (Figure 7) and hypocotyls (Zaragoza *et al.*, 2004; Kanwar *et al.*, 2003, respectively). This procedure seemed to be unnecessary for leaf and stem explants.

Figure 7 Regeneration of black locust shoots on PPT-containing medium

2.4.5 Transgene integration

Gus activity was detected by X-gluc (5-bromo-4-chloro-3-indolyl β -D-glucuronide) assays in callus growing on a kanamycin-containing medium (Kanwar *et al.*, 2003) and on leaves isolated from transgenic plants regenerated in the presence of hygromycin or PPT (Igasaki *et al.*, 2000; Zaragoza *et al.*, 2004). GUS activity was also determined by the MUG assay, showing that enzyme activity was higher in transgenic lines than in nontransformed plants, with values ranging from 6.5 to 12.8 nM 4-methylumbelliferone (4-MU)/mg protein/min in transgenic plants versus 0.17 nM in controls (Igasaki *et al.*, 2000).

The integration of the *hpt* and *bar* transgenes was confirmed by PCR and Southern hybridization. No variation in the number of copies of the *hpt* gene was observed since all the three transgenic plants assayed integrated a single copy of the transgene. On the contrary, three out of the six plants analyzed for the *bar* gene showed a single insertion of the gene and the other three had two insertions of the gene. The stability of the *bar* transgene in the micropropagated transgenic plants was confirmed periodically by PCR analysis (Zaragoza *et al.*, 2004). Kanwar *et al.* (2003) did not report any molecular characterization on the integration of the *nptII* gene.

CR assays showed that all *bar* PCR-positive plants induced changes from red to yellow indicating that phosphinothricin acetyl transferase (PAT), the enzyme encoded by the *bar* gene, was able to detoxify PPT and ammonium was not accumulated (Figure 8).

Herbicide tolerance assays performed on excised leaves and whole transgenic plants demonstrated that the level of PAT expression in these plants was high enough to confer resistance to ammonium glufosinate. Control plants died 4 days following herbicide application, while transgenic plants survived and leaves remained green (Figure 9).

From the literature reviewed, it can be concluded that it is possible to regenerate phenotypically normal transgenic *R. pseudoacacia* plants using *Agrobacterium* strains and that several genes can be used as selectable markers (*nptII*, *hpt*, and *bar*). Results, however, differ among authors. Igasaki *et al.* (2000) suggested that neither kanamycin nor geneticin were suitable selection

Figure 8 CR assay: control plant (right) and two *bar*-positive transgenic plants (left)

Figure 9 Herbicide assay: two controls (left) and three *bar*-positive (right) black locust plants 4 days after herbicide application

agents for black locust since nontransgenic calli grew up in the presence of these aminoglycosides. Similar results were obtained when cotyledons were infected with LBA4404 carrying the vector pBI121 (Arrillaga, personal communication) or following particle bombardment of PEMs with the same plasmid (Arrillaga and Merkle, 1994). These findings, however, are inconsistent with the reports of Han *et al.* (1993), Ahn (1995) and Kanwar *et al.* (2003) all of whom used kanamycin for selection following *A. tumefaciens*- or *A. rhizogenes*-mediated transformation.

3. FUTURE ROAD MAP

Black locust is among the most widely planted tree species in the world because it is ornamentally attractive, drought tolerant, fast growing, fixes nitrogen, has very hard, durable wood, and is adaptable to many sites and climates. In spite of the biological and economic importance of the species, and its amenability to both tissue culture and genetic transformation, the actual impact of biotechnological tools on the genetic improvement of black locust to date has been minimal. In fact, with the exception of a paper reporting herbicide (glufosinate ammonium)-resistant transgenic black locust (Zaragoza *et al.*, 2004), there is no work reporting engineering of black locust with genes of potential economic importance. Thus, the transformation challenge for the near future in black locust must lie in extending the established protocols to genes of interest. The recently completed sequencing of the *Populus trichocarpa* genome (Tuskan *et al.*, 2006) would facilitate, by sequence comparisons, the identification of genes that are likely to be involved in producing valuable traits in black locust. Among potentially valuable genes are those related to pest and disease resistance, improved wood characteristics, and faster growth. Taking into account the well-known uses of black locust, the biotechnological approaches that may have a high impact for the genetic improvement of the species are as follows:

- (1) Pathogen and pest resistance. Black locust is severely damaged by insects and disease, probably more so than any other eastern US

- hardwood species. Ubiquitous attacks by the locust stem borer (*M. robiniae*), locust leaf miner (*O. dorsalis*), and by the heart rot fungi *P. rimosus* and *P. robinophilus* make growing black locust for timber production impractical. Thus, one of the first goals may be to engineer the tree with genes conferring insect or disease resistance, as has been demonstrated in other hardwood species (Giri *et al.*, 2004).
- (2) Manipulation of wood formation. Advances are being made toward describing developmental mechanisms regulating secondary growth in trees (Groover and Robischon, 2006). In black locust, various genomic tools, including expressed sequence tags and complementary DNA microarrays, have been employed for the study of wood formation (Yang *et al.*, 2003, 2004; <http://biodata.ccgb.umn.edu>). All these advances, in conjunction with the genome sequence of poplar, should provide the identification of black locust genes that control wood formation, a prerequisite for any transgenic strategy aimed at altering the rate of wood biogenesis and properties of wood.
 - (3) Yield improvement. The increasing economical pressure for wood and wood products may require use of intensive management of plantations with genetically engineered trees to produce biomass efficiently (Boerjan, 2005). This is of particular interest for black locust, since the species has been a focus of attention for biomass production for fuel. Since black locust is a leguminous tree, efforts in this field should be primarily focused on the improvement of the nitrogen fixation process and subsequent ammonia assimilation. Another important approach that could contribute to increased yield is the modulation of cell wall extensibility by up- or downregulation of genes implicated in cell wall metabolism. Tree size, morphology, and performance can be also accomplished through modifications in plant hormone levels (Giri *et al.*, 2004). Finally, the prevention of flowering could be another strategy to increase vegetative growth; one way of achieving this might be to express cytotoxic genes from floral-specific promoters (Skinner *et al.*, 2000).
 - (4) Phytoremediation. Because of their large biomass and longevity, trees are an ideal tool for phytoremediation, the use of plants to stabilize, reduce, or detoxify pollutants in soil or water. Given the successful deployment of black locust on mine spoils (Merkle and Nairn, 2005), the tree may be a suitable target for engineering with phytoremediation genes.
 - (5) Black locust metabolomics. In addition to the genome sequence and methods to analyze the transcriptome, a comprehensive analysis of phenotypes and biological processes will require metabolomics, a tool that is generally much less developed (Boerjan, 2005). This attains a special significance in black locust, which has been cited as having a number of interesting traditional medicinal uses, as well as being poisonous to man and animals. However, as Tian *et al.* (2001) state, few chemical investigations have been conducted to identify the active principles in this plant. In fact, these authors identified an unusual compound (robinlin), a novel C-11 homo-monoterpene, with strong bioactivity in the brine shrimp lethality test. Thus, the identification of all the metabolites of the species (their metabolome) and measurements of their dynamics under many different challenges will be of paramount importance. Integrated approaches combining metabolomics with transcriptomics and proteomics may contribute to the metabolic profiling of black locust in the near future. This also will facilitate the identification of genes associated with pest and disease resistance as well as novel metabolites of biomedical interest.
 - (6) Marker-assisted breeding programs. The use of genetic maps based on molecular markers linked to genes of interest facilitates the selection of simple and complex traits, thus accelerating their incorporation into breeding materials. Also, molecular markers are utilized for the characterization of the population structure (the distribution of variability within and between populations) and in paternity testing. Although markers have been utilized in many hardwood tree species, there have been no studies of this type in black locust.

Sandalwood

Christopher G. Jones and Julie A. Plummer

School of Plant Biology, University of Western Australia, Crawley, Western Australia, Australia

1. INTRODUCTION

1.1 Taxonomy, Distribution, and Ecology

Sandalwood is the general name given to a small group of parasitic shrubs or trees in the genus *Santalum*, family Santalaceae. The taxonomic and molecular phylogeny of these species has recently been reviewed, with a comprehensive summary on 16 species and their variants (Harbaugh and Baldwin, 2007). Members of the genus *Santalum* are widespread, growing throughout India, Indonesia, Australia, New Guinea, Hawaii, and many South Pacific islands. The term sandalwood refers to those species that bear fragrant heartwood and have been utilized commercially for this purpose. *Santalum album*, often referred to as East Indian or tropical sandalwood has long been harvested for its valuable, odorous wood (Rai and Sarma, 1990). The genetic origins of *S. album* appear to be East and West Timor, as well as a small population in northern Australia (Harbaugh and Baldwin, 2007). A more detailed study of the Indo-Papuan species *Santalum macgregorii* and *S. album* in particular has found few mutations in the chloroplast genome, suggesting recent speciation (C. Jones *et al.*, in preparation). In India, it occurs throughout the Indian subcontinent, particularly in the southern states of Karnataka, Kerala, Tamil Nadu, and Andhra Pradesh (Rai, 1990). *Santalum spicatum* is one of Western Australia's oldest export industries and it is still harvested commercially. To a lesser extent, *Santalum lanceolatum*, commonly known

as “plumbush” or northern sandalwood, has been harvested in Queensland and South Australia (Applegate *et al.*, 1990b; Statham, 1990; Applegate and McKinnell, 1993). In the Pacific, *Santalum yasi*, *Santalum austrocaledonicum*, and *Santalum insulare* were extensively utilized (Jiko, 1993; Ehrhart, 1998).

Sandalwoods are slow growing root hemiparasites, meaning they derive some water and nutrients from the roots of neighboring trees and shrubs (Loneragan, 1990; Radomiljac and McComb, 1998; Radomiljac *et al.*, 1999; Tennakoon and Cameron, 2006). Host trees vary, depending on the *Santalum* species and their native ecosystem. In India, *S. album* utilizes a wide range of hosts, and occasionally self-parasitizes (Rai, 1990). *S. album* occurring in Timor similarly parasitizes numerous species, including *Eugenia guajava*, *Casurina junghuhniana*, *Cassia siamea*, *Schleichera oleosa*, and *Pterocarpus indicus* (Suriamihardja and Suriamihardja, 1993). In Australia, *S. spicatum* associates with *Acacia accuminata* and *Eremophila* spp. while *S. lanceolatum* is often found in association with *Acacia cambagei* and *Melaleuca* spp. (Applegate and McKinnell, 1993). Growth rates for each species will vary according to rainfall, soil type, and climate. Tropical *S. album* may take 40–60 years to reach maturity (Rai, 1990).

In contrast, *S. spicatum* is the slowest growing species taking up to 100 years to reach a commercial size (Applegate *et al.*, 1990a). Inflorescences of *Santalum* spp. are usually auxiliary or terminal cymose panicles, petals are 4- or 5-merous,

fused to the perianth, and purple-brown in color (Hewson and George, 1984). The flowers have inferior ovaries yielding one single-seeded drupe. Flesh of the fruit is typically purple; however, *S. spicatum* fruits are dry and fibrous, enclosing a hard nut (Hewson and George, 1984). Although only limited work has been done on the cytological features of sandalwood, root-tip squashes have indicated that *S. album* is diploid and has 20 chromosomes (Kulkarni *et al.*, 1998). Other members of the genus are believed to be tetraploid, particularly the non-oil-yielding *Santalum acuminatum* (Byrne *et al.*, 2003b) and Papua New Guinean *S. macgregorii* (C. Jones *et al.*, in preparation). Several other species within the genus may also be polyploid, and this is currently being investigated (D.T. Harbaugh, personal communication). *S. album* and *S. spicatum* are outcrossing insect-pollinated trees; however, self-pollination is possible (Rugkhla *et al.*, 1997).

1.2 History and Economic Importance

All of the commercially utilized sandalwoods are pulled from the ground at harvest, the upper limbs are cut, and bark removed. Logs are then cut into billets, which are either processed or exported directly (Loneragan, 1990). Usual downstream processing involves grinding the wood into a fine powder and processed into incense or joss sticks. These are used in many Asian ceremonies and religious events (Loneragan, 1990; Rai and Sarma, 1990). The ground wood is also distilled by either hydro- or steam-distillation to produce the neat oil, often used as a fixative for many perfumes. Supercritical CO₂ has been utilized as an alternative to distillation with similar results (Piggot *et al.*, 1997; Moretta *et al.*, 1998). *S. album* yields more heartwood oil than other members of the genus, with typical values around 6.2% (w/w) (Shankaranarayana and Parthasarathi, 1987; Verghese *et al.*, 1990; Shankaranarayana *et al.*, 1998). Extractable oil yield can vary from zero to nearly 9% (w/w) from within one tree (Jones *et al.*, 2006). *S. yasi* from Fiji is reported to yield about 5% oil, *S. austrocaledonicum* around 3–5%, and *S. spicatum* around 2% (Applegate *et al.*, 1990a).

Sandalwood oil production from India is variable. However, the Food and Agriculture

Organization of the United Nations reports an estimated 40 tons per annum over the period of 1987 to 1993 (Anonymous, 1995). Indonesia, the world's second largest producer of *S. album* products, produced an average of 15 tons of oil per annum for the same period. In the 10 years from 1995 to 2005, Indonesia provided the bulk of *S. album* products to the world markets, while India's production levels fell significantly due to scarcity and legislated resource protection. In March 2006, the highest auction price in India for cleaned *S. album* logs was Aus\$105 400 per ton (Source: Tropical Forestry Services Pty. Ltd, Australia).

Sandalwood, despite being a renewable plant resource, is suffering from significant decline in India, Indonesia, the South Pacific, and Australia. This is primarily due to overharvesting and illegal poaching of native stands, or by biological hindrance from grazing animals or sandal spike disease (Loneragan, 1990; Rai and Sarma, 1990; Statham, 1990). Harvesting of *S. spicatum* from native stands is likely to continue for some time although considerable effort is going into developing the species into an extensive plantation crop (Radomiljac, 1998; Brand, 2002; Woodall and Robinson, 2002a, b). In Western Australia, *S. spicatum* and *S. album* are being planted in the southwest and far north of the state, respectively. Plantations of *S. album*, as well as small plots of *S. austrocaledonicum* and *S. macgregorii*, are being trialed at the Frank Wise Agricultural Research Station, Kununurra, Western Australia. The oldest *S. album* trees from these trials are approaching 20 years, and preliminary experiments have shown yields of valuable heartwood oil after 10 years. *S. lanceolatum* is being trialed in Queensland (Bristow *et al.*, 2000), while a concerted effort to re-establish *S. austrocaledonicum* as a tree crop is also underway in Vanuatu (Tate *et al.*, 2006). *S. insulare* from eastern Polynesia is critically endangered due to overharvesting, and as such a conservation program is being implemented (Butaud *et al.*, 2005).

1.3 Traditional Breeding and Improvement Programs

Despite being utilized for centuries, sandalwood has received little attention from a tree improvement perspective. Efforts to understand the complex ecology of the species have largely

hampered field trials, and as such most tree improvement work has been devoted to selection of superior phenotypes from naturally occurring populations. Heritability studies for desirable traits such as tree form, health, early heartwood onset, high heartwood content, and essential oil yield have not been conducted extensively. Although once complete, these investigations would certainly provide a solid rationale for further tree improvement.

Probably the most significant steps toward genetic improvement of sandalwood species have been through genetic diversity studies: identifying restriction fragment length polymorphisms (RFLPs), microsatellite or simple sequence repeat polymorphisms, and random amplified polymorphic DNAs (RAPDs). By gaining some measure of the level of variation within and between sandalwood populations, researchers have been able to assess potential for improvement. *S. spicatum*, *S. austrocaledonicum*, *S. album*, and *S. insulare* have been studied intensively in this regard. *S. spicatum* was assessed for genetic diversity using both nuclear and chloroplast RFLP probes (Byrne *et al.*, 2003a, b) revealing modest levels of genetic variation but few rare alleles and considerable inbreeding coefficients compared to other widespread forest species such as *Eucalyptus* spp. (Hines and Byrne, 2001). Although this particular study used anonymous alleles, these polymorphisms may represent genotypic variation in gene structure and function, which could in turn affect important phenotypic traits such as form, growth rate, and heartwood oil production. *S. austrocaledonicum*, a sandalwood tree confined to the South Pacific islands of Vanuatu and New Caledonia, was recently examined for population structure and genetic diversity using microsatellite markers (Bottin *et al.*, 2005). In contrast to *S. spicatum*, *S. austrocaledonicum* has a very limited distribution, bound by ocean in all directions, significantly restricting gene flow and germplasm dispersal. This probably explains the high mean fixation index, sometimes referred to as the inbreeding coefficient F_{is} , compared to *S. spicatum*. On the basis of this comparison, one may predict that there is considerable scope for improvement in *S. spicatum* compared to *S. austrocaledonicum*; however, caution must be exercised when comparing different techniques and unknown alleles. Whilst microsatellites and

RFLPs represent co-dominant genetic markers, meaning data can be pooled for most forms of analyses, the analytical methods are fundamentally different. Often, the detected polymorphisms may not be directly related to functional genes.

S. insulare, a sandalwood growing throughout the French Polynesia was studied intensively by chloroplast microsatellite polymorphisms (Butaud *et al.*, 2005). As populations of *S. insulare* are restricted to islands, gene flow between populations was particularly low. About one-third (36%) of the total genetic diversity was between archipelagos, 31% between islands within a given archipelago, and 33% within islands. Further studies on the same populations found that clonality was common, and that up to 58% of the trees examined were likely to be clones of another individual (Lhuiller *et al.*, 2006). Clonal reproduction in nature is common for many species of sandalwood. *S. lanceolatum* in Victoria, southeastern Australia, for example, is represented by only one small population of clones (Warburton *et al.*, 2000). The level of genetic variation in *S. lanceolatum* in its northern distributions (Queensland, Northern Territory and northern Western Australia) is not well understood. Clonal reproduction of *S. lanceolatum* has been used to advantage, as regrowth from pulled trees appears to result in healthier root suckers (Bristow *et al.*, 2000).

Genetic diversity in *S. album* has been studied using isozyme variation (Suma and Balasundaran, 2003) and RAPDs (Shashidhara *et al.*, 2003; Suma and Balasundaran, 2004). Both these techniques have helped researchers to understand the extent of diversity remaining within the natural distribution of sandalwood in India. Unfortunately, no comprehensive study has included Indonesian material, although a study by RFLPs of *S. album* growing in northern Western Australia has included some Timorese material for comparison (C. Jones *et al.*, in preparation).

Of all of the work compiled on the genetic diversity of *S. album*, the consensus seems to be that while little diversity exists within populations, there appears to be significant diversity between natural populations. Suma and Balasundaran (2003) found that 78% of all variation was described by differences between populations, while the remainder was within individual populations. The populations studied

were geographically isolated (several hundred kilometers apart) with different climatic zones. Gene flow is hence quite low between populations. Shashidhara and co-workers (2003) found that RAPDs were effective in distinguishing genotypes and estimating relatedness. Levels of genetic dissimilarity were low (15%) between nearby populations, and high (91%) when compared to *S. spicatum* (the designated out group). This would be expected as *S. spicatum* is unique to arid southwestern Australia and resides some 6000 km away. However, when the out group was excluded from the same analysis, 75% was the highest level of genetic dissimilarity. From these findings one may conclude that the level of genetic diversity for *S. album* in India is sufficient for a tree improvement program. Traditional breeding methods for woody perennials, most notably open-pollinated seed orchards, are well established for many forest species, particularly *Eucalyptus* (Chaix *et al.*, 2003). Seed orchards have been established for *S. album* in India and Australia using this principle. The phenotypes of the progeny seed collected from such orchards are difficult to assess due to natural variability in the plantation environment. While RAPD is an accepted means for estimating relatedness, the technique has been shown to overestimate within-population variability in the absence of a suitable out group (Powell *et al.*, 1996). In the Forest Products Commission collection of *S. album* in the Ord River Irrigation Area, Kununurra, Western Australia, genetic variation estimated by RFLPs was low, but phenotypic variation in oil yield was quite substantial. This may be due to subtle nucleotide sequences undetected by this technique (C. Jones *et al.*, in preparation).

In addition to genetic improvement, improved plantation management has taken the sandalwoods to a new level of productivity. For many years, the seemingly simple process of growing seedlings, planting them in the field, and maintaining trees until harvest has been very difficult and often inefficient. It was not until the early 1990s that research into suitable silvicultural practices was conducted, and eventually a fairly reliable production system for *S. album* was published (Radomiljac, 1998). Likewise, *S. spicatum* recently underwent a similar research (Brand, 2002; Woodall and Robinson, 2002a, b). In both instances, it was essential for

a short-term pot host to be grown alongside *Santalum* sp. seedlings. At the time of planting into the field, a medium-term host must be well established nearby and a suitable long-term (longer than 5–7 years) host must eventually be present. Sufficient haustorial connections must be made in the early stages of development. Since all of the sandalwoods are root hemiparasites, early host–parasite relationship is key to their survival. In a recent comprehensive study of the histology and anatomy of *S. album* haustoria, Tennakoon and Cameron (2006) found that proto-haustoria will develop in young seedlings, which remain unattached to host roots. But the formation of a penetration peg, which taps into a host's root xylem is not present in these immature organs. Once attached to the host, a peg is formed. Furthermore, the presence of parenchymous tissue in the host–parasite border supports the hypothesis that cross-membrane solute transport is occurring, and hence some solute selectivity could be involved. Most significantly for the plantation industry, if this process is selective in terms of the nutrients and chemical signals that are moved from host to sandalwood tree, the influence of host species and root connectivity is bound significantly to affect tree growth, vigor, and essential oil productivity.

Not surprisingly, the complex ecology of the sandalwoods makes phenotypic selection difficult. Plant nutrient and water demands are complicated further by host contributions, as well as planting density, pruning regime, and light penetration/requirements. All of these factors contribute to the overall health and vigor of the sandalwood tree, making genetic selection fraught with error. Simple oil yield and heartwood content analysis of standing trees have been used as a selection tool (Jones *et al.*, 2007), but the genetic contribution to any variation identified is substantially masked by agronomic practices and variations in environment niches across the plantation.

In the last 20 years, tissue culture has provided some useful avenues into large-scale clonal propagation of sandalwood. Somatic embryogenesis (Rao and Bapat, 1995; Rugkhla and Jones, 1998; Rai and McComb, 2002) along with molecular studies on intra- and interspecific hybrids (Rugkhla *et al.*, 1997; McComb and Jones, 1998) have been major advances, and trees cloned

in this fashion have shown growth characteristics comparable to naturally regenerated trees. The ability to clonally reproduce large numbers of specific genotypes is essential for any future transgenic work. Currently, tissue culture technique is proving useful for propagation but the process is expensive and time consuming, and application to genetic transformation is lacking.

Unlike the usual applications of tissue culture for plantlet regeneration, Valluri *et al.* (1991) devised a process whereby *S. album* cell cultures were grown in a bioreactor where phenolic compounds were measured as an indicator of secondary metabolic activity. This rationale ensured that the optimum growing abiotic conditions were discovered before further exploitation of the system. Bioreactors offer the benefit of having all necessary genetic machinery operating in a hygienic, controlled environment.

1.4 Scope for Transgenics in Sandalwood

Clearly, traditional tree improvement methods can, and should be, used to deliver more desirable trees. However, the application of transgenic technology to sandalwood may offer a faster route to the same end. One cannot disregard the value of knockout or knock-down sandalwood genotypes to improving our understanding of gene structure, transcription, and regulation. Further to experimental applications, highly active promoters may be introduced to economically important genes such as terpenoid synthases, prenyltransferases, and transcription factors.

Unfortunately, almost none of the *Santalum* genome or transcriptome has been sequenced, let alone functionally characterized. A thorough evaluation of all relevant genes is essential before embarking upon the introduction of foreign genes to sandalwood. The long rotation time for sandalwood trees is probably the main driving force to develop transgenic lines. Traditional crossing and selection trials would take at least 40 to 50 years to evaluate; provided a suitable phenotype screen is established (i.e., one that accounts for environmental variability). Given the long period between harvests for sandalwood, this may not be of concern. However, if genetically superior seedlings could be identified at the nursery stage, or even propagated *in vitro*, growers could

plant sandalwood with certainty of better long-term returns.

2. TRANSGENICS DEPLOYED SO FAR AND POTENTIAL OPTIONS FOR THE FUTURE

2.1 Current Status

Transgenic sandalwood has only ever been produced in two experiments, both a decade apart. In 1998, a proof of principle experiment by Veena and Rao (1998) inserted the bacterial derived marker genes β -glucuronidase and the selective gene neomycin phosphotransferase II (*NPTII*) bound by a binary vector were inserted into the *S. album* genome using *Agrobacterium tumefaciens*. A suite of binary vectors containing the marker genes were trialed: pKIWI105, pBI121, and pIG121-Hm. Of these pKIWI105 proved to be the most efficient. Standard assays for *GUS* (β -glucuronidase) and *NPTII* were used to select transformed *S. album* embryos, and polymerase chain reaction (PCR) with insert-specific primers confirmed that the new genes were present in the regenerated seedlings.

The vectors pKIWI 105 and 110 are binary vectors, which have been used previously in other plant gene transformations (Janssen and Gardner, 1989; Yao *et al.*, 1995). The transfer-DNA (T-DNA) component of the vector inserted into *S. album* used a nopaline synthase promoter (*NOS*) to drive expression of *NPTII* gene, enabling kanamycin-based antibiotic selection. The construct also contained a P35S cauliflower mosaic virus promoter to drive expression of the *uidA* gene (encoding the β -glucuronidase enzyme). *GUS* expression was restricted only to true positives by utilizing defections in both pKIWI105 and pIG121-Hm. The *uidA* gene in pKIWI105 lacked a ribosomal binding site while the vector pIG121-Hm contained an intron in the same gene construct. This ensured that *GUS* expression would only occur under plant transcriptional machinery and not bacterial.

Veena and Rao (1998) used PCR to confirm the presence of *GUS* genes and hence cells were shown to be transgenic; however, the shoots emerging from infected embryos were chimeric. Chimeras are a common problem, although

repeated subcloning may have eventually rectified this. Until recently, this was the only example in the literature of the introduction of foreign genes into a sandalwood species. Just this year, Shekhawat *et al.* (2008) repeated the experiment, only instead of using cotyledon stage plantlets, embryogenic cell suspension cultures of *S. album* were infected with *A. tumefaciens* containing the pCAMBIA 1301 vector. Stable, high level GUS protein expression was noted. Both experimental procedures relied heavily on tissue culture technique, indicating the application of transgenics to sandalwood will be slow for some time.

Although not technically a transgenic experiment, there is a growing body of evidence that gene transfer between parasitic plants and their hosts has occurred in the past, resulting in polyphyletic distributions (Nickrent *et al.*, 2004; Davis *et al.*, 2005). While still poorly understood, there may be some merit to the possibility of genetic information being transferred between morphologically and genetically distant angiosperms. If this is the case, then there is considerable potential for transfer of specific genes via the parasitic connections sandalwoods have with their hosts. Further work is clearly needed to investigate this phenomenon.

2.2 Potential Application of Resistance Gene Transfer

There are many potential applications for the insertion of foreign genes into sandalwood, not least resistance to sandal spike disease. Spike disease is a major concern for growers in India, where the majority of natural stands remain. Symptoms include yellowing of leaves and in severe cases defoliation, poor form, and low fruit set. Efforts to combat the phytoplasma responsible for the disease have been made, but follow-up research is lacking (Lakshmi Sita, 1996; Khan *et al.*, 2004). If resistance genes were to prove useful against spike disease, there is certainly potential to insert them into the genome of sandalwood. To this end, Lakshmi Sita and Bhattacharya (1998) isolated and cloned a proline-rich protein (PRP) complementary DNA from *S. album* leaves. PRPs serve as biopolymers involved in the maintenance of cell wall integrity, and may be involved in systemic resistance to pathogens. At present, this appears to be the only functional genetic

analysis of potential resistance mechanisms in sandalwood. Further work in this area is certainly needed.

2.3 Potential Improvement by Metabolic Engineering

Sandalwood is highly prized for essential oils contained within the heartwood. The oils consist of the sesquiterpene alcohols α -santalol, β -santalol, α -trans-bergamotol, and *epi*- β -santalol. These compounds make up nearly 90% of the distilled oil (Verghese *et al.*, 1990). These appear to be the 12-hydroxy products of the olefin precursors, α - and β -santalene, α -bergamotene, and *epi*- β -santalene. Other minor compounds make up the remainder of the extracted oil. The biosynthesis of these oils appears to occur in the transition zone between sapwood and heartwood (Jones *et al.*, 2006).

Terpene biosynthesis begins with the 5 carbon unit of isopentyl pyrophosphate (IPP). This compound is synthesized from either the mevalonic acid pathway, localized in the cytoplasm of cells (Gershenzon and Croteau, 1990; Dewick, 2002), or it can be derived from plastids via the deoxy-D-xylulose 5-phosphate pathway (Arigoni *et al.*, 1997; Rohmer, 1999). Condensation with the isomer of IPP, dimethylallyl pyrophosphate (DMAPP) leads to the universal 10 carbon monoterpene precursor geranyl pyrophosphate (GPP). Further condensation with DMAPP leads to the 15 carbon farnesyl pyrophosphate (FPP) while the diterpene precursor geranyl geranyl pyrophosphate (GGPP) is derived from a third condensation with DMAPP (Gershenzon and Croteau, 1990).

Terpene synthases (TPS) are responsible for converting the linear precursors GPP, FPP and GGPP into cyclic compounds. Scores of TPS have been isolated from a vast array of plant species and most have been functionally characterized by either heterologous expression in *Escherichia coli* or from cell-free extractions. The TPS gene family is large, with high homology among taxonomic groups (Bohlmann *et al.*, 1998). Many of these genes encode proteins that catalyze the formation of multiple products (Munck and Croteau, 1990). Site-directed mutagenesis studies by Hyatt and Croteau (2005) found that only very subtle amino

acid changes can have a large impact on the terpenoids produced.

Sandalwood oil biosynthesis has only recently received detailed attention. Our research group has found strong correlations between the santalenes and bergamotene, suggesting multiple product formation from a single TPS in *S. album* (Jones *et al.*, 2006). This work has been followed up with gene isolation, functional characterization, and expression studies (C. Jones *et al.*, in preparation). The gene structure and expression properties of TPS in sandalwood may be exploited through modification or selection of specific genotypes conducive to high essential oil production.

However, before this kind of work can proceed, one must understand the normal pattern of oil formation in wild-type sandalwood. Normally, in the case of *S. album*, fragrant heartwood does not form until around 10 years (Rai, 1990) and it continues to expand outward as the tree matures. Ideally, a tree worthy of selection would yield heartwood earlier, and the ongoing expansion of fragrant heartwood would continue throughout the tree's life at a faster rate. At some point in the first few years of tree development, a signal induces oil biosynthesis. Interestingly, almost all members of the *Santalum* genus yield sesquiterpenes; and even the related African sandalwood *Osyris tenuifolia* (Santalaceae) produces sesquiterpenes in its heartwood. All of these species are root parasites, so it is curious to note the link between root parasitism and secondary metabolite formation in vascular tissues.

As detailed by Tennakoon and Cameron (2006) the haustorial connection involves exposure to soil-borne pathogens, which may in turn elicit oil production. Oil biosynthesis appears to be localized to ray parenchyma (Jones, unpublished results), which seems logical as only ray parenchyma cells are metabolically active. Studies linking host species and haustorial connection to oil yield have not been compiled. Such investigations would surely present a valuable insight into this phenomenon. With respect to transgenic sandalwood, expression of the sesquiterpene metabolic pathway is probably controlled very tightly until a certain age; suggesting that overexpression may cost the plant significantly. Terpenoids are highly reduced chemicals that bear a considerable metabolic cost (Gershenzon, 1994), so production of sesquiterpenes must be limited

until sufficient photosynthetic capacity is attained. A comprehensive knowledge of secondary metabolism pathways and their regulation in sandalwood is required before it can be exploited.

Another potential application of transgenics in sandalwood is the knockout of undesirable genes. For example, *S. spicatum* attracts a lower value than Indian sandalwood for various reasons, one being the complex mixture of sesquiterpenes in the extracted oil. One of the many sesquiterpene compounds present in distilled oil is farnesol (Piggot *et al.*, 1997; Howes *et al.*, 2004). Farnesol has been implicated as a potential allergen (Hostynek and Magee, 1997; Schnuch *et al.*, 2004). If the farnesol synthase gene could be silenced or excised from the genome, the allergenic properties of the distilled oil may be reduced. At present, the distilled oil may be rectified by fractional distillation and preparative chromatography, such that farnesol can be isolated from the oil. While the application of farnesol-free transgenic sandalwood may seem rather superfluous, it would at least provide an immediate commercial use of knockout sandalwood lines.

2.4 Potential for Transforming Sandalwood Genes into Other Organisms

Further to transforming sandalwood with foreign genes, sandalwood genes may be inserted into other species. There is growing interest in this technology as the santalene chemical structure is particularly difficult to synthesize (Christenson and Willis, 1980; Krotz and Helmchen, 1994; Zhong and Schlosser, 1994). Transformation of faster growing annual plants with synthase genes derived from *Santalum* may provide a quicker and easier route to the complex tricyclic santalenes. There is a growing body of research confirming multigene transformations, including the recent transformation of caffeine biosynthesis in tobacco (Uefuji *et al.*, 2005). *E. coli* or yeast can also be engineered to produce medicinally important plant metabolites, as has been proven with the antimalarial compound artemisin (Chang and Keasling, 2006). Sandalwood fragrances may also be produced in the same way, while careful regulation of the cytochrome P 450 responsible for hydroxylation of the santalenes completes the process. Oil yields may be low compared to that

of a mature tree; however, the process can be automated for a continuous supply.

New compounds are still being discovered in various sandalwood species (Brunke *et al.*, 1995; Kim *et al.*, 2005). Some chemicals found in sandalwood tissues have shown potential for medicinal benefit (Kim *et al.*, 2006). It may be possible to engineer these compounds into host plants, fungi, or bacteria as their natural abundance in sandalwood is too low to be economically feasible.

2.5 Testing of Transgenic Sandalwood

If sandalwood were to be transformed with genes for pathogen resistance or increased essential oil production, the product would require rigorous testing. Again to do this, uniform field trials must be established along with nontransformed controls. At present, this is particularly difficult given the aforementioned issues with growing parasitic trees. Glasshouse trials would be useful for initial pathogen resistance tests; however, the long-term expression patterns of the gene(s) would need to be monitored and confirmed in the field. Heartwood oil yields can be monitored over time using established nondestructive sampling techniques (Jones *et al.*, 2007). As no mapping projects have been undertaken on sandalwood, nor has the genome been extensively sequenced, this will be difficult and time consuming. Nonetheless, if transformation of new genes into sandalwood is successful and the desired outcomes are expressed in the phenotype, growers will want the ability to continue growing these trees from seed.

Studies on sandalwood mating systems are somewhat deficient in the literature. Rugkhla *et al.* (1997) found that both *S. spicatum* and *S. album* were preferentially outcrossing; however, both species were able to self-pollinate. Fruit development and seed set also depended heavily on genotype. In circumstances where clonal propagation has occurred and genotypes are appropriate, self-pollination can occur and produce viable seed. This process must be taken into consideration if transgenic sandalwood species are released. Seed collected from these plants will also require testing to confirm hereditary patterns. Further crosses must be done in order to obtain a relatively pure line; however, this will take considerable time given

the long rotation cycle of sandalwood plantations. Flowering and fruit production are observed after only a few years, but the transgenic traits may not be revealed for many more years. It may also be necessary to plant the transgenic sandalwood at some distance from natural populations as cross-pollination is likely to occur. This should apply to all genetically improved plantations whether they are transgenic or bred using more traditional methods.

2.6 Regulatory Measures Adopted

In Australia, all genetic engineering and biotechnology regulation is covered by the Commonwealth Government Office of Gene Technology Regulator. Legislation is covered extensively in the *Gene Technology Act 2001*, and all research, development, and extension is bound by this act. Release of products created through transgenic technology is covered by other offices; in the case of foodstuffs the Australian and New Zealand Food Safety Authority and for other products, including potential transgenic sandalwood products, the Therapeutic Goods Administrator.

Indian transgenic research is also bound by legislation covered by the *Environmental Protection Act 1986*, and the rules concerning genetic engineering were added in 1989. Several governing authorities are responsible for monitoring the research and release of genetically engineered goods, particularly the Ministry of Environment and Forests and the Department of Biotechnology. Any transgenic work on sandalwood that is done in either of these sandalwood producing countries is bound by the regulations set out by these authorities.

3. FUTURE ROAD MAP

3.1 Product Expectations

While there is certainly potential for transgenic sandalwood or other plants with sandalwood genes to be developed, there is often a large disparity between promised qualities and actual results. Production of transgenic woody plants is not a trivial task as it often relies heavily on tissue culture. Strong selective markers have improved

the odds of acquiring positive transformants, but the random location within the genome of an insert could make their regulation more difficult to follow.

Therefore, the following approach for transgenic research in all economically and noneconomically important sandalwoods should be adopted. A significant and sustained genetic mapping project should be undertaken, along with sequencing as much of the genome as possible. Genetic diversity studies should be followed up with gene flow and mating system studies, such that breeders will have known parameters in mind when performing crosses and developing new seed lines. Expression studies should be initiated concurrently, investigating transcriptional and metabolic responses to the many environmental factors that affect sandalwood growth and development. Functional characterization of as many secondary metabolic pathway genes should also be carried out and correlated with metabolite profiles *in vivo*. Extensive field trials must be established with all variables controlled, such that systematic processes can be fully explored. Promoter regions and transcription factors for many important pathways should also be considered; the sequences of these regions must be deduced.

Once these significant barriers to understanding normal gene expression in the sandalwoods are brought down, transgenic lines can be considered. Trials of different techniques of transformation should be considered. For example, gene-gun technology has not yet been trialed in sandalwood, and may prove more efficient than bacterial transformation. If young sandalwood flowers are inoculated with *Agrobacterium*, and the embryos transformed, the need for tissue culture could be avoided (Clough and Bent, 1998). Selectable markers like antibiotic resistance could be optimized, and the use of herbicide resistance constructs may also improve selection. Retention of herbicide resistance qualities in regenerated sandalwood plants may be useful, as weed management in plantations often risks killing sandalwood via weed-parasite haustorial connections.

3.2 Addressing Risks and Concerns

Transgenic sandalwood faces the same challenges and uncertainties as every other transgenic

organism produced to date. The public have grown wary of transgenic technology and the outrageous promises often claimed. Sandalwood is perceived as a natural product, far superior to any man-made chemical perfume. The same market that desires natural sandalwood will also question any transgenic lines of sandalwood, or even metabolically engineered bacteria as “unnatural”. Europe is a major producer of perfumes, and one of the largest customers of sandalwood oil. Current bans on genetically engineered products may hamper any efforts to test this technology. No doubt that organizations that intend to capitalize on transgenic sandalwood will have a strong marketing challenge ahead of them.

But in addition to marketing, the product must be safe and unlikely to harm consumers, or natural populations of sandalwood. Ultimately, the product must actually work and deliver the desired properties for which it was created. The sandalwoods have a very low weed risk, given the demise of their natural distribution. Hence, it is unlikely that transgenic lines will “escape”.

On the basis of current status of the technologies, market, and industry, transgenic sandalwood is unlikely to attract much commercial attention in the near future. Growing the plant under normal conditions and traditional breeding methods are already challenging enough. Furthermore, as the product is well established and has been shown to yield fragrant heartwood under plantation conditions, the need for transgenics is still low.

3.3 Expected Technologies

Transgenic sandalwood as a final product represents only part of the technology. As researchers seek to understand the genetic control of essential oil production, further applications in other species may become apparent or indeed using *ex planta* systems. Little work has been done since 1998, suggesting that modern techniques could be used to optimize transformation and selection. New transfer DNA (T-DNA) vectors and genotypes of *Agrobacterium* have since been developed, and are likely to work far more efficiently than those described by Veena and Rao (1998). Tissue culture free techniques of transformation should also be considered, particularly flower-dipping inoculation. *Santalum*

inflorescences vary widely, but generally have large numbers of individual flowers per stem. This would save considerable time but may in turn result in fewer transformants. Recognizing the natural promoters and terminators of the sandalwood genome will also help determine the make up of T-DNA constructs. Comparison of TPS and their regulatory elements among the *Santalum* genus will substantially aid our understanding of divergence in yield and composition.

Teak

Emilio Mendoza-de Gyves and Eddo Rugini

Dipartimento di Produzione Vegetale, Università degli Studi della Tuscia, Viterbo, Italy

1. INTRODUCTION

Teak (*Tectona grandis* Linn f.) is a deciduous forest tree species whose timber possesses several qualities. It is one of the world's premier hardwood timbers, rightly famous for its mellow color, fine grain, and durability. Other qualities include many properties such as attractiveness in lightness with strength, ease of working and carving, and resistance to termites, fungi, weathering, seasoning capacity without splitting, cracking, or materially altering shape. It has a good stability in fluctuating climates, strength, and decorative grains of wood. Teak is one of the most studied forest species due to its wide geographical distribution even in far places from its natural distribution. In fact, Tewari (1992) refers in his book "A Monograph of Teak" to more than 3000 papers on teak during more than 150 years including the most diverse aspects of the utilization of teak.

1.1 History, Origin, and Distribution

Teak is indigenous to continental Asia and is confined to the moist and dry mixed deciduous forest below 1000 m altitude in India, Myanmar, Thailand, and Laos. This species is also well established in Indonesia, but it is not clear whether this occurrence is natural or the results of an introduction by Hindu settlers in the 7th century. It is believed that teak was introduced to Java 400–600 years ago from India (Tewari, 1992). Due to its high timber qualities, high market demand, and ease of growing and domestication, teak plan-

tations have been widely established throughout the tropics since the 1850s. It has been widely planted between the latitudes of 28° N and 18° S in Asia and the Pacific region, as well as in Africa and Latin America. Under exotic conditions, plantations of the species has been successfully established in many countries including Sri Lanka, Bangladesh, and China in Asia; Ghana, Nigeria, Ivory Coast, Senegal, Togo, Benin, Sudan, and Tanzania in Africa; Trinidad and Tobago, Costa Rica, Puerto Rico, and Panama in Central America; and Brazil and Ecuador in South America. Teak planting in India began in the 1840s. Teak plantations were established in temporary association with agricultural crops, in Myanmar in 1856, and in Indonesia around 1880. The first introduction outside Asia was in Nigeria in 1902, with seed from India and Myanmar. Plantations in Ghana started around 1905 and in Côte d'Ivoire in 1929. The first teak plantation in tropical America was established in Trinidad and Tobago in 1913 with seed from Myanmar. Planting of teak in Honduras, Panama, and Costa Rica started at the end of the 1930s. There was a gradual increase in the area of teak plantations between the 1950s and 1960s. One of the major areas under teak plantation is in Java, Indonesia (Pandey and Brown, 2000).

1.2 Botanical Distribution and Taxonomy

Teak belongs to the genus *Tectona* and family Verbenaceae (Table 1). The name *Tectona* is derived from the Greek word "tekton", which

Table 1 Botanical classification of teak

Category	Name
Kingdom	<i>Plantae</i>
Division	<i>Magnoliophyta</i>
Class	<i>Magnoliopsida</i>
Order	<i>Lamiales</i>
Family	<i>Verbenaceae</i>
Genus	<i>Tectona</i>

means carpenter, while the name of a species “*grandis*” stands for large in Latin. The genus *Tectona* is represented by only three species: *T. grandis* Linn. f., *T. hamiltoniana* Wall., distributed in the dry zones of Myanmar, and *T. philippinensis* Benth and Hooker. f., confined to the Philippines islands (Tewari, 1992).

Because teak is a deciduous tree, generally teak trees remain leafless in winter and become dormant in their growth. Further, they also become leafless or exhibit dry nature of foliage during dry spells in summer and show apparent decrease in growth (Rajendrudu and Naidu, 1999). It can reach more than 30 m in height in favorable conditions. Crown opens with many small branches. Bark is brown, distinctly fibrous with shallow, longitudinal fissures. The rotation period is approximately 80 years. The root system is superficial, often no deeper than 50 cm, but roots may extend laterally up to 15 m from the trunk. Teak has somatic chromosome number of $2n = 36$ (Hedegart and Eigaard, 1965).

Teak is able to grow under a wide range of climatic and edaphic conditions. Optimal temperatures are from 25°C to 28°C, but teak can adapt to extreme temperatures. The annual rainfall should be between 1250 and 2500 mm, although teak has been found in some places with a 600 mm annual rainfall and in places with almost 4000 mm. The altitude range of growth is 0–1200 m in soils with a pH of 6.5–8 and good drainage. Teak grows very fast, particularly for a hardwood. It produces between 12 and 26 m³ of wood per year. Teak plants possess a great ability to overcome water stress (Rajendrudu and Naidu, 1997).

Teak has small flowers, found on the topmost branches in the unshaded part of the crown. Fruit is a drupe with four chambers. Each fruit may contain from zero to four seeds. One kilogram contains 1000–3500 seeds. Flowers normally have six petals in a ring. An inflorescence can contain

several thousand buds, but not all of them develop during flowering (Bryndum and Hedegart, 1969). Teak clones with a larger corolla tube diameter show higher fruit set (Vasudeva *et al.*, 2004). Pollen grain of teak has two shapes, prolate spheroidal (fertile) and perprolate (infertile) with a ratio of 3:2 between the forms (Choldumrongkul *et al.*, 2000).

According to a study on dry matter production in the reproductive components, from a massive flower production only about 0.5–0.7% flowers developed into fruits. Immature fruit abscission totaled 34% and 58% of the total number of fruits initiated in the 14- and 30-year-old trees, respectively (Karmacharya and Singh, 1992). Small fruits, with less than 9 mm diameter have low germination percentage leading to a less number of seedlings (Indira *et al.*, 2000).

Teak displays true annual rings, which are useful for determination of age and growth rate of the trees in wood production of managed stands. The occurrence of false rings often misleads the task of age and growth rate determination as continuous or discontinuous false rings are more frequent in juvenile teak (Priya and Bhat, 1998).

1.3 Economic Importance

In the first half of the last century, teak was one of the most important forest tree species in the tropical countries. However, with the development of pulp and paper industry in the last years, the main attention was turned toward plantations with fast growth like that of eucalypts and acacias.

1.3.1 Area coverage

The global planted teak area of the world as recorded in 1990 was about 1.6 Mha (million hectares), which is equivalent to about 75% of the high-grade tropical hardwood plantations. Based on the available information, it is estimated that there is a total of over 28 Mha of natural teak forest around the world. Details of teak resources in the Asia Pacific region are provided in Table 2. Some salient points on the Asia Pacific region are identified in the overview of the global teak resources as follow: from about 1.6 Mha of teak plantation in the world, the 99% occurs in Asiatic regions; from about 28 Mha of natural teak forest,

Table 2 Teak resources in the Asia Pacific region (area in hectare)^(a)

Country	Natural forest	Plantations	Total resources	Data up to
Bangladesh	–	62 700	62 700	1985
China	–	900	900	1992
India	8 900 000	276 640	9 276 250	1975
Indonesia	–	675 640	675 640	1990
Laos	16 000	5000	21 000	1992
Malaysia	–	3859	3859	1994
Myanmar	16 517 700	219 485	16 737 185	1994
Philippines	–	21 550	21 550	1990
Sri Lanka	–	70 813	70 813	1992
Thailand	2 500 000	170 240	2 670 240	1990
Vietnam	–	2037	2073	1994
Regional Total	27 933 700	1 516 674	29 450 374	

^(a) Source: Teaknet newsletter, Issue No. 1, December 1995 (Ko Ko Gyi and Kyaw Tint, 1995; Status of Management of Natural Teak Forest, presented at 2nd Regional Seminar on Teak, Myanmar)

the 60.5% occurs in Myanmar, indicating this country as dominant in the production of naturally grown teak; India possesses the second place for area with 31.2% of the total teak resources in Asia; Thailand is third with 9.2% of the total teak resources in Asia; Indonesia is the country with the largest teak plantation area in Asia, covering 47% of the total teak plantation area in the Asiatic region. Of the total area of forest plantations in 1995 in the entire world, 42.7% were softwoods and 57.3% were hardwood species, including the most valuable hardwoods: teak, mahogany, and rosewood (Krishnapillay, 2000; Pandey and Brown, 2000).

1.3.2 Production

Indicative estimates of teak standing volume (industrial wood) annually available place Asia as the dominant producer. According to five case studies, in Malaysia, the Melanesian Islands, Central America, Australia, and Ghana, governments have a significant role in initiating hardwood plantation development (Varmola and Carle, 2002). Besides governments' help, several other aspects have influenced teak forest production during the last decades: the worldwide reduction of the supply of tropical wood from natural forests; the extension of teak to zones very far from its natural distribution; the growth of forest products in the international market and the appearance of new centers of consumption; the advances in the processing technologies giving

other alternatives; the greater attention paid to the ecological aspects of the forests in its sustainable exploitation (Graudal *et al.*, 1999).

Size is more important influential feature in harvesting than age of maximum volume production because teak is planted for timber production. Its natural rotation age range can vary between 50 and 90 years, while the optimum commercial age is between 50 and 60 years. The average actual of mean annual volume increment at rotation age is $3 \text{ m}^3 \text{ ha}^{-1}$ per year. Some teak plantations have been established relatively recently in most countries outside its natural range. Thus, the most production of teak is largely restricted to the traditional large producers: Myanmar, India, and Indonesia. One of the most recent estimates provides an indicative total annual production of teak roundwood of $1\,795\,000 \text{ m}^3$ (Pandey and Brown, 2000).

1.3.3 Utilities

Establishment of forest plantations is not a popular activity among farmers because of the long time it takes for them to convert any income from the operations. Poor farmers generally cannot risk the long-term investments and credit. A combined system to produce food, livestock, and timber is necessary to allow them to take part in the potentially lucrative teak production (Roder *et al.*, 1995). Intercropping offers farmers the opportunity to obtain some benefits in the meantime, including those obtained for savings in

pest management due to increased diversity. Type of crop, spatial arrangements of plants, planting rates, and maturity dates must be considered when planning intercrops. Some studies to identify suitable crops for growing in interspaces of teak were carried out. *Trifolium alexandrinum* and *Vigna* beans could be grown with a minimum reduction in yield (Dagar *et al.*, 1995). Soybean mixed with teak not only makes the latter to grow better but also allows harvesting of the bean for food. Rice can be intercropped for the first 3 years.

1.3.4 Other economic attributes

Teak possesses optimal characteristics for the most variable uses. Its wood is a medium-weight timber that is rather soft. Grain is straight, wavy, or slightly interlocked, with rather coarse and uneven texture (Brennan and Radomiljac, 1998). Teak trees have a mean basic density of 610 kg m^{-3} and mean air-dry density of 700 kg m^{-3} . They present good basic wood properties (i.e., green density, basic density, air-dry density, and shrinkage), as well as recoveries, sawing and drying behavior, and working properties (i.e., sawing, sanding, color, planning, nailing, and staining), indicating this species to show potential for value addition (Brennan and Radomiljac, 1998). The wood grains are figured well, producing an attractive veneer, which is extensively used in the manufacture of furniture and interior fittings. The teak wood can be used for bridge building and constructions in contact with water since it possesses excellent characteristics of durability and resistance. In fact, it is used for ship decking and other construction works such as boat building. In house building, teakwood is often used for floors and for garden furniture. Among other attributes widespread throughout the world are the multiple uses, such as the fabrication of boxes, musical instruments, and toys, and particularly it is used for building poles, transmission line poles, fence posts, and railway sleepers.

1.3.5 Other potential industrial uses

Lapachol, a naphthoquinone, has been isolated from teak. This compound causes a dermatitis allergy and gives the wood resistance to termites

(Schmalle and Hausen, 1984). Researchers have found that lapachol has promising anticancer and antiviral properties. It has been shown that this compound is active against leukemia cells and fungi (Perry *et al.*, 1991). It has also been evaluated for its estrogenicity and antinidational activity in mice (Sareen *et al.*, 1995). Teak callus is able to produce triterpene acids, which show a potent antibacterial activity against *Escherichia coli* and *Bacillus subtilis*. These compounds occur in small quantities in the intact tissues and are not easily detected (Marwani *et al.*, 1997). From the root heartwood of teak, a compound, 5-hydroxylapachol, has been isolated and it has been found to be a cytotoxic agent (Khan and Mlungwana, 1999). Extractives present in the heartwood of teak are believed to be responsible for its durability. Several studies of teak heartwood extractives and decay resistance showed that most teak heartwood extractives directly contribute to the natural durability of teak (Supriana, 1988). The presence of tectoquinone extractive is a good indicator for the estimation of the resistance against wood-destroying fungi. Decay resistance increases from the pith to the sapwood and is also related to the age, rate of growth, and extractive content. Particularly, tectoquinone was identified as a bioactive compound for the inhibition of *Coniophora puteana*, a strong fungus that causes wood decay (Haupt *et al.*, 2003). Deoxylapachol is a precursor of tectoquinone (Sandermann and Simatupang, 1968). Juglone is another aromatic organic compound found naturally in teak bark. Juglone exerts its effect by inhibiting certain enzymes needed for metabolic function of other organisms. This extract of teak bark has shown its effectiveness against *Listeria monocytogenes* and methicillin-resistant *Staphylococcus aureus* (Neamatallah *et al.*, 2005). Leaves of teak are rich in phenols, poor in proteins, contain traces of alkaloids, and are free from flavonoids, steroids, and saponins (Tripathi *et al.*, 1998). Pathak *et al.* (1988) found betulin aldehyde from the bark of teak to be an antitumour agent. In traditional medicine, a wood powder paste has been used against bilious headaches and swellings, and internally against dermatitis or as a vermifuge. The bark has been used as an astringent and the wood as a hair tonic (Perry and Metzger, 1980). A natural colorant can be extracted from leaves containing a yellow or red dye used for dyeing silk, cotton,

and wool (Vankar *et al.*, 2003; Mahale *et al.*, 2004).

1.4 Traditional Breeding

Teak has a large natural variability due to its wide distribution. It can survive and grow under a wide range of climatic and edaphic conditions. This large variation determines an important genetic resource to be used in genetic improvement.

Identification of *plus* trees from natural forests and plantations has been carried out as a part of the teak improvement programs. A *plus* tree is considered an individual phenotypically outstanding, combining a number of desirable traits. In selecting *plus* trees of teak, each superior tree is compared with at least five trees within a radius of 50 m from the *plus* tree. In order to determine the superiority of the *plus* tree, a scoring system is adopted for characters such as height, diameter, clear bole height, straightness of stem, branching pattern, resistance to pests and diseases, and for seed production (Subramanian *et al.*, 1994). In forestry, the definition of *Provenance* is not only to determine the place of origin, but also to determine a variety of other things including population, country, etc., even from a place where the species is not native. According to the definition of Burley and Wood (1976) provenance refers to any place where trees are situated, indigenous or not, while the term origin can be used to refer to the place of which the species is native. The interaction between provenance and environment is the main problem that a breeder has to solve, choosing the most suitable seed source (provenance) for planting at a particular site (Matheson and Raymond, 1984).

1.4.1 Breeding objectives

A preliminary evaluation of important genetic characteristics has been carried out on provenances. The parental combining ability has been tested in breeding programs. The information obtained helped to find clones with good characteristics. High estimates of both heritability and genetic gain have suggested the predominant role of additive gene action. The

selected teak clones have been included in breeding (Kumar *et al.*, 1997; Mandai, 1999). Among the observed characters, diameter growth and stem straightness and clear bole, persistence of stem axis, and flowering habit (early and/or late flowering) are strongly inherited in this species (Harahap and Soerinegara, 1977; Keiding *et al.*, 1986).

In addition to teak natural plantings in Asia, the domesticated plantations in Africa and Central America have been taken into account for obtaining further variability. The selection of individuals adapted to local climates and soils may have formed “landraces” in these new areas, with different distinctive characteristics (Kjær and Foster, 1995). Some characteristics have been associated with leaf morphology to facilitate phenotypic identification (Rawat *et al.*, 1998).

Finding variability for transferring resistance to pests and diseases has been another objective. Insect defoliation provokes deep wood anatomical changes in juvenile teak plants. Some studies have demonstrated a much better performance in growth of teak when protected from insect defoliation, suggesting that genetic improvement is worth considering (Priya and Bhat, 1997). The larva of *Eutectona machaeralis* (Lepidoptera: Pyralidae) is an important pest of teak leaf skeletonizer included in the breeding programs (Roychoudhury and Joshi, 2000). Another serious problem is the collar rot of teak, which is a major nursery disease caused by *Rhizoctonia solani* (Ramesh, 2000).

1.4.2 Tools and strategies

Kjær *et al.* (1999) mentioned the basic strategies used in teak for tree improvement. Breeding seedling orchards (BSO) consists of a combining test of mother trees with commercial seed production managing the breeding populations within the seed orchards. It results in economical and faster delivery of improved seed; however, less genetic gain and low seed production per tree make the system less suitable for improvement of teak. Extensive breeding seed orchards (EBSO) is a modified system to collect seed for multiplication from a large area covered with a large number of selected trees established from a bulk seed

lot. The seedlings are multiplied by cutting stems. Multiple population breeding strategy tests trees planted under variable conditions (cultural practices). It is limited to the possibility of manipulating the environment. This strategy allows faster results and more flexibility in tree improvement. The selected clones are subdivided into groups taking different criteria into account.

Biotechnology has introduced new means to study genes and their functions and to assist breeding programs through the use of genetic markers. Molecular markers help in the detection of differences among individuals at the level of DNA. In addition to analyzing genetic diversity within the populations and locating genes that determine economically important qualities (rate of growth, adaptability, quality of the wood, etc.), genetic markers provide approaches for the study of evolutionary processes in plant populations (Cruzan, 1998). Several studies of forest trees, including teak, have shown larger differentiation between adaptive traits than between biochemical markers (Kjær and Siegmund, 1996). Among the populations examined, those genetically most diverse within and among populations of the species should merit a high priority for conservation. Combination of marker-aided population genetic analysis and information about adaptive and quantitative traits as well as forest ecosystems allows for the development of a conservation program (Changtragoon, 2001).

1.4.3 Achievements

1.4.3.1 Elite tree selection

During the last century, selections of *plus* trees were made in both natural and established plantations. These selections were made based mainly on their phenotypic appearance. Some help was obtained from the molecular marker identification but only in the last 15 years. The selections were introduced into seed orchards. The production of control-pollinated seed collected from these orchards was subsequently tested and then used for operational reforestation. A variety of breeding designs were employed to create genetic tests to rank the selections, estimate genetic parameters,

and make new selections for the second generation. Complementary mating designs were carried out focused on clonal forestry and application of techniques from molecular genetics and biotechnology (Tewari, 1992; Kaosa-Ard, 1995; Kaosa-Ard *et al.*, 1999).

1.4.3.2 Mass propagation of elite material

Establishment of new industrial forest plantations requires long time. To enhance teak plantation development, governments of producer countries have been making efforts to focus the research on improvement of the establishment of seed and clonal orchards to make the elite planting materials available for mass multiplication.

1.4.3.3 Propagation by seed

Teak is traditionally reproduced through seeds, but in most cases, germination is difficult due to the hard seed coat, low seed quality, and low fruit setting. The nature of barriers that prevent seed germination can be physiological (germination inhibitors in the mesocarp), physical (thick and hard endocarp), or morphological (the requirement of after ripening associated with hormone imbalance in seeds), which results in only the old drupes showing moderate germination. Poor germination rate leads to a low production of seedlings (Hedegart, 1973; Egenti, 1981; Kaosa-Ard, 1995; Bonal and Monteuuis, 1997; Palupi and Owens, 1997; Tiwari *et al.*, 2002). To overcome this problem, the forced-aged treatment on the fruits has been proposed by placing them in an ageing chamber maintained at 100% relative humidity and 40 °C up to 15 days for increasing their germination percentage (Dharmalingam, 1995). Chacko (1998) suggests that the system of termite-aided mesocarp removal of teak fruits is an efficient presowing treatment for early and enhanced germination. The rooting time of seedlings is 8 to 15 days, and the survival rate of rooted stock is 90–100% (Dabral, 1976; Gupta and Kumar, 1976; Unnikrishnan and Rajeev, 1990; Tewari, 1992). Some improvements in the overall performance of seeds have been done using γ -irradiation (Bhargava and Khalatkar, 1987).

1.4.3.4 Propagation by cuttings

Vegetative propagation using juvenile seedlings has also been developed on a commercial scale. Although rooting of cuttings has been a serious problem, several procedures have been set up to improve rooting by means of auxin treatments. Indole-3-butyric acid (IBA) treatment appears to be the product mostly used in promoting of roots formation. It has been found to be the most effective auxin tested (Palanisamy and Subramanian, 2001; Castro *et al.*, 2003). The combined application of IBA and rice bran extract enhances considerably adventitious rooting in semi-hardwood shoot cuttings of teak (Ansari *et al.*, 2004). The effect of auxin in rooting promotion is more effective in mature cuttings (Husen and Pal, 2006). Cutting production is more expensive than seedling production; however, the cutting option is considered better because it results in genetically stable material (Monteuuis *et al.*, 1995; Kaosa-ard *et al.*, 1999).

1.4.3.5 Micropropagation

Vegetative multiplication of teak using *in vitro* techniques by means of axillary bud stimulation is expected to be a very effective way to capture the best genetic stock from the breeding program in shorter time. In spite of the progress made in tissue culture of teak since the 1970s (Narasimhan *et al.*, 1970; Dhruva *et al.*, 1972; Gupta *et al.*, 1980; Gill *et al.*, 1991; Devi *et al.*, 1994; Monteuuis *et al.*, 1998; Tiwari *et al.*, 2002; Castro *et al.*, 2003; Yasodha *et al.*, 2005), it still remains problematic due to the poor capacity of shoot proliferation, high susceptibility of shoots to vitrification and browning, and the low frequency of *in vitro* rooting. *In vitro* rooting is often preferred to an *ex vitro* system in terms of plant quality due to the advantage of already possessing roots during the acclimatization phase (De Klerk, 2002). However, in most of the tissue culture laboratories that produce teak plants in the world, rooting is still done *ex vitro* due to the low frequency of *in vitro* rooting (Tiwari *et al.*, 2002; Castro *et al.*, 2003; Yasodha *et al.*, 2005; Singh *et al.*, 2006). Recently, an efficient micropropagation method including an efficient *in vitro* rooting methodology was proposed focused on large-scale industrial

plantations by using *plus* plants (Mendoza-de Gyves *et al.*, 2007). This method, which produces multiple shoots of high quality (Figure 1), takes in consideration a short micropropagation cycle consisting in the transference of excised nodal segments from the newly formed shoots onto a fresh medium. Following this protocol, more than 800 shoots can be obtained from single internodal segment explant in 3 months (an average of almost four shoots with four internodes each). The procedure includes a fast soaking in a gibberellic acid solution (100 mg l^{-1}) for an elongation within the same step of propagation and overcomes problems of vitrification by reducing the ammonium quantity of the MS (Murashige and Skoog) salts medium and by adding pectin of must of wine (Migros, Switzerland) to reduce the water content in the medium. Elongated shoots are transferred onto the rooting medium for 4 weeks of incubation using the combination of IBA (0.5 mg l^{-1}) with putrescine (160 mg l^{-1}). Putrescine promotes both strong and ramified roots and fast-growing shoots during the rooting phase and subsequently in the pots and in combination with IBA rooting reaches 100% conditioning the plantlets for a better acclimatization performance. Plant acclimatization after rooting with IBA + putrescine guarantees 100% success. The use of exogenous polyamines to increase *in vitro* rooting and to improve root quality was first demonstrated in olive, which had similar problems like teak for rooting. Polyamines combined with auxins promote early rooting and increase the final rooting percentage and the number of roots per explant (Rugini and Wang, 1986; Rugini *et al.*, 1993).

1.4.3.6 Marker-aided selection

At present, there are numerous molecular techniques for identifying genetic markers. They have considered documentation of the genetic diversity of teak in various geoclimatic populations (provenances). The results are helping in identification of quantitative trait-specific loci within individuals and populations and selection of superior parents for inclusion in the breeding program.

Genetic differentiation between populations of teak was examined in some quantitative characters and allozyme loci. Large differences

Figure 1 Micropropagation of teak: (a) 1-month-old multiple shoots of high quality in proliferation phase from nodal explants; (b) rooted microcutting ready to be transplanted into pot; (c) comparison between rooting treatments: 0.5 mg l^{-1} of IBA (left) and 0.5 mg l^{-1} of IBA + 160 mg l^{-1} of putrescine (right) (note that the presence of putrescine allowed strong and more ramified roots); (d) potted plant after acclimatization phase

between populations were found in the quantitative traits. Regional patterns were found, but there were also substantial variations within ecological–geographical defined regions (Laos, Thailand, West India, and Indonesia). A much less pronounced differentiation between populations was found in allozyme markers (Kjær *et al.*, 1997). In other studies, the gene diversity was carried out using isoenzyme analysis in teak provenances in order to measure and to monitor the biodiversity in tropical and temperate forests. Fourteen enzyme systems were analyzed in leaf parenchyma of nine native and introduced populations of teak. A cluster of two main gene pools was shown in this analysis. The cluster showed two main gene pools: the first one consisted of the Indian provenances and the second of African, Indonesian, and Thai provenances. Genetic distances among populations of the same group were similar, and lower than the genetic distances between populations from different groups (Kertadikara and Pratt, 1995). Isoenzyme analysis was also used in the determination of carbonic anhydrase activity in teak for studying its relationship with

photosynthesis. Carbonic anhydrase may serve as a biochemical marker for photosynthetic capacity in teak genotypes (Tiwari *et al.*, 2006).

Shrestha *et al.* (2005) analyzed some patterns of genetic variation within and among nine populations of teak from diverse geographical regions in India, Thailand, and Indonesia. They used amplified fragment length polymorphism (AFLP) for this analysis. Their results showed that 57% of total genetic variance occurred within populations while the remaining 43% occurred between populations indicating that Indian populations are clearly separated from those from Thailand and Indonesia.

Microsatellite loci have also constituted a useful tool for investigating the mating system, gene flow, parentage, and population dynamics for use in sustainable management of natural teak forests and for *in situ* conservation purposes. Verhaegen *et al.* (2005) developed some polymorphic microsatellite loci from a genomic library enriched for AG/TC repeats. Their work describes the development of 15 microsatellite markers for teak. Primers used to amplify these loci were tested on 265

individual trees from different teak populations (India, Thailand–Laos, Indonesia, and Africa). The number of alleles ranging from 3 to 20 per locus was clearly higher in India and Africa than in Indonesia and Thailand–Laos. In all cases, the observed heterozygosity was lower than expected.

A discrimination among teak plus trees was done by Watanabe *et al.* (2004) by using selected random amplified polymorphic DNA (RAPD) markers to achieve a highly reliable clone management. They performed a primary screening for 120 arbitrary decamer primers, selecting 24 primers that generated 26 clear and unambiguous fragments. In a subsequent screening, they investigated the reproducibility of each fragment by six repetitions of polymerase chain reaction, and finally selected 13 fragments found to be most reproducible. RAPD markers were also used to analyze genetic fidelity but using micropropagated teak clones with respect to subcultural passage (Gangopadhyay *et al.*, 2003). No variation in RAPD profiles was noticed in the *in vitro* clones of several passages in comparison to the *in vivo* mother plants. Only one micropropagated plant of 25th subcultural passage showed a new polymorphic DNA fragment.

Genetic diversity was evaluated in populations of teak in Thailand by means of the identification of RAPD loci revealing that about 21% of the total variation was attributable to differences among populations. The number of polymorphic loci in most of the investigated populations was very high with an average of 72.6%. The average expected heterozygosity was 0.31. Significant differences in allelic frequencies were found between populations (Changtragoon and Szmidt, 2000). The natural populations of teak in Thailand were found to be highly differentiated genetically. It suggests that materials from at least one population of each province in the northern and central part of Thailand may be required for both *in situ* and *ex situ* gene conservation purposes (Changtragoon, 2001).

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

Conventional breeding methods have certain limitations in teak, including long rotation age, difficulties in performing controlled pollination, low germination percentage, and low genetic

variability of the species. These limitations make genetic engineering an important tool.

1.5.1 Long rotation age

As in other woody plants species, the use of sexual hybridization for improvement of teak is a slow, lengthy process. The long juvenile period of teak seedlings ranging between 6 and 8 years per generation cycle is a major limitation for rapid improvement of teak. Thus, the wood quality of progeny often cannot be assessed for several years. Resistance to certain diseases cannot be confirmed until after several years have passed. The development of new genotypes by breeding and selection results in a long and tedious task. In most instances, only the F₁ generation can be selected (Kaosa-ard, 1986; Kjær and Foster, 1995).

1.5.2 Difficulties in performing controlled pollination

Pollination is one of the most important activities to control in forest tree breeding programs. Among the factors that limit the development of controlled-pollination technique of teak are as follows: its high allogamy degree, the only 1-day life of the flowers, and its very short pollination period (2–3 h). Teak trees can start flowering when they are 6–10 years old. Under controlled pollination, the highest percentage of self-compatibility is only 5.5% as compared with crossing, which is as high as 60% (Bryndum and Hedegart, 1969; Hedegart, 1973; Karmacharya and Singh, 1992; Kaosa-Ard, 1995; Tangmitcharoen and Owens, 1997; Silikul, 2000).

1.5.3 Low germination percentage of seed

Fruit setting is also considered important for any breeding program. Although a massive number of small flowers occur throughout the flowering period (4–5 months), only a small quantity of seed can be collected from each tree. Teak has a very low conversion of flowers to fruits (0.5–2%). This low fruit percentage is due to the low proportion of pollinators to flowers and the short flowering and pollination periods of individual

flowers (Bryndum and Hedegart, 1969; Hedegart, 1973; Egenti, 1981; Kaosa-Ard, 1995; Palupi and Owens, 1997).

1.5.4 Low genetic variability

The potential of teak germplasm remains underexploited due to insufficient genetic variability for traits in question. Problems such as resistance to the teak defoliators, *Hyblaea puera*, *Walterianella* spp. and resistance to teak skeletonizer (*Paliga damastesalis*), which are serious pests in homogeneous plantations of teak, resistance to fungal pathogens, *Nectria* spp., causing canker on trees, and improvement in postharvest attributes, yield, and economic returns cannot be solved because variation is limited (Bhowmick and Vaishampayan, 1989; Baksha and Crawley, 1995; Arguedas and Quirós, 1997; Kalia *et al.*, 1998; Intachat, 1999; Leuangkhamma and Vongsiharath, 2005). Only one natural resistance in some teak clones has been reported against its prime insect pest, *Eutectona machaeralis*, which could offer a viable long-term solution to the leaf skeletonizer menace (Roychoudhury *et al.*, 1997). The use of biotechnological techniques for the genetic improvement of teak is, therefore, essential for overcoming the limitations of conventional breeding.

2. DEVELOPMENT OF TRANSGENIC TEAKS

2.1 Donor Gene

Until now, application of only one useful gene has been reported, the *CryIA(b)*. It was used in microprojectile bombardment into embryos of teak using a plasmid containing the *CryIA(b)* gene of *Bacillus thuringiensis* (*Bt*) subsp. *kurstaki*. The plasmid contained the *hpt* (hygromycin phosphotransferase) and the *gus* (β -glucuronidase) genes under the regulation of the promoter and terminator sequence from 35 transcript derived from cauliflower mosaic virus (CaMV). *CryIA* is one of the *Bt* genes that have been cloned to provide resistance to insect pests. It encodes crystalline proteins in the bacteria that are responsible for larval toxicity. When eaten by the insects, these crystalline, or *Cry* proteins, bind to

the insects' midgut causing those cells to burst from a water imbalance finally killing the insects. Transgenic plants containing a *Bt* gene produce these *Cry* proteins, which the insects ingest when feeding on the plants (Gill *et al.*, 1995; Keeton *et al.*, 1998).

2.2 Transformation Methods

2.2.1 Employment of gene gun

Genetic engineering could offer a very important contribution to genetic improvement of teak. This technology may help to circumvent some of the limitations of classical breeding programs associated with teak improvement. An attempt for engineering insect resistance into teak genome was done. Norwati *et al.* (2003) reported transformation of teak tissues using the particle bombardment method by utilizing highly regenerative calli coming from nodal segments. Explants were subjected to bombardment with gold particles coated with plasmid DNA carrying *hpt* as a selective gene, *gus* as a marker gene, and *CryIA(b)* gene coding for a *B. thuringiensis* toxin. Explants were then transferred onto the medium for shoot development. Elongated shoots were then subcultured onto the same medium supplemented with hygromycin (10 mg l⁻¹) for selection. After a culture period of some months with 6-week subculture intervals in a selection medium containing hygromycin, some plants expressed β -glucuronidase activity by staining with X-gluc (5-bromo-4-chloro-3-indolyl β -D-glucuronide). Polymerase chain reaction (PCR) analysis confirmed transgene's integration into the plant genome. No test with *CryIA(b)* gene expression was reported.

2.2.2 *Agrobacterium*-mediated transformation

Widiyanto *et al.* (2003) selected transformed calluses previously co-cultivated with *Agrobacterium tumefaciens* LBA 4404 strain carrying the pBI121 binary vector and *GUS* gene. Selected calluses were transferred into the callus-induction medium consisting of the woody plant medium (WPM) supplemented with thidiazuron (TDZ)

and indole-3-acetic acid (IAA). The derived transgenic calluses were selected on the same medium containing 100–200 mg l⁻¹ kanamycin. The addition of 10 μ M 6-benzylaminopurine (BAP) and gibberellic acid (GA3) induced shoot formation on selected callus tissues after 4–6 periods of subcultures. The kanamycin-resistant shoots showed positive *GUS* expression. Subsequently, Widiyanto *et al.* (2004) compared two strains of *A. tumefaciens*, the LBA4404 and GV3101, as the hosts for binary vectors, the pBI121 and the pCAMBIA1303 respectively, both containing the *GUS* gene as marker to evaluate the transformation efficiency. The strains differed from each other for antibiotic-selecting gene: the first one contained *nptII* (neomycin phosphotransferase II) gene, whereas the second one contained *hpt* gene and an additional marker gene, the *mgfp5* (green fluorescence protein). Transformation experiments were carried out by co-cultivation of the bacterium with shoot explants for 10–15 min before placing them on the medium, consisting of WPM supplemented with TDZ (1.0 μ M) and IBA (0.01 μ M). Transient expression of *GUS* gene, observed after 72 h of co-cultivation, varied from 5% to 80% depending on shoot tissues, plant genotype, and bacterium strain. The strain LBA4404 was highly effective on gene expression in all clones.

2.3 Selection of Transformed Tissue

Evaluation and setting up of both the transformation methods were carried out with the aid of selection of antibiotic resistance markers, *hpt* (encoding hygromycin resistance), and *nptII* (encoding kanamycin resistance). These antibiotic resistance genes have allowed that transformed cells express them to be selected for out of populations of nontransformed cells. The selection used in the transformation methods showed a good performance since *hpt* (10 mg l⁻¹) and *nptII* (50 mg l⁻¹) genes are well known, and commonly used throughout the world.

2.4 Regeneration of Whole Plant and Activity Testing

Despite the progress made in the last 20 years by using plant molecular approaches to improve

some forest trees (Parsons *et al.*, 1986), the success of teak transformation has been limited. Regeneration of plants from single cells, tissues, and organ explants is the main requirement for *in vitro* genetic manipulation. It is known that an optimal *in vitro* regeneration offers new prospects for rapid and efficient introduction of desirable traits in selected trees (Diouf, 2003). In teak, as in other forest trees, regeneration is still difficult to achieve from somatic tissues.

Kushalkar and Sharon (1996) designed a system to regenerate teak via somatic embryogenesis. They obtained callus using apical buds of teak on the MS medium supplemented with BAP (0.1 mg l⁻¹), NAA (α -naphthaleneacetic acid) (0.01 mg l⁻¹), and 3% sucrose. Callus formed globular and heart-shaped somatic embryos when transferred to the half-strength MS liquid medium containing BAP (0.1 mg l⁻¹) + NAA (0.1 mg l⁻¹). They also found a direct system to obtain somatic embryos from axillary buds of teak on the half-strength MS liquid medium containing BAP (1.0 mg l⁻¹) + 2iP (1.5 mg l⁻¹) using filter paper bridges.

In other studies, Yunaini and Widiyanto (2003) examined the influences of BA (benzyladenine), TDZ, and GA3 to induce somatic embryogenesis in teak. They obtained compact callus with nodular structures from leaf explants cultured in the WPM liquid medium supplemented with 0.1–1.0 μ M TDZ in combination with 0.01–1.0 μ M IBA. They used embryogenesis-induction media enriched with 8.0 μ M BA or 1.0 μ M TDZ obtaining early stages of somatic embryos. Compact callus cultures generated clusters of globular and heart-shaped embryos. The addition of GA3 (2.0 μ M) enhanced positive responses when used in combination with BA or TDZ. The subsequent torpedo and cotyledonary stages were completed after 4–6 weeks in the culture medium containing 3–4.5% sucrose without growth regulators.

The few available reports on plant regeneration of teak show the difficulty in obtaining recovery of whole plants from somatic tissues. The recalcitrance of teak has been the major obstacle in the entire genetic manipulation process. Although somatic embryogenesis from leaf explants was reported (Yunaini and Widiyanto, 2003), the transformation trials carried out in teak were accomplished using calli formed from internodal

segments and meristems. The use of these tissues induces the formation of organogenetic callus from internodal segments (Daquinta *et al.*, 2001; Widiyanto *et al.*, 2005). Norwati *et al.* (2003), using gene gun method, reported regeneration of plantlets selected onto the medium enriched with hygromycin that expressed β -glucuronidase activity. Even if the integration into the plant genome was confirmed by PCR analysis, no expression test with *CryIA(b)* gene inserted was reported. As regards the experiments using *Agrobacterium*-mediated method, Widiyanto *et al.* (2003) and Widiyanto *et al.* (2004) reported elongated shoots in the presence of antibiotics (*hpt* and *nptII*) and the transient expression of *GUS* gene for estimating transformation efficiency. No transgenic whole plant was reported.

3. FUTURE ROAD MAP

The potential applications of gene transfer technology to all branches of agriculture are increasing. It is quite likely that within the next 20 years, genetic improvement will routinely utilize gene transfer, at least adjunctively. However, recalcitrant species like teak will not be in the advance phase in the next few years. Teak will be in disadvantage in comparison to other forest plants and crops, making it less profitable and replaceable. Forest researchers are looking at a range of other possible transformation methods capable of improving the technique extending to those species that are still difficult to be easily manipulated.

3.1 Genetic Improvement Expectancy

Taking into account the possibility of improving the genetic transformation procedure in teak, it will be focused on solving the main agronomic and commercialization problems by transferring of foreign genes or by limiting the expression of the endogenous ones. The main desirable traits to transfer in teak would include the following: (a) reduction of its reproductive cycle; (b) yield increase; (c) wood quality improvement; (d) abiotic stress tolerance; and (e) pest and disease resistance. At present, several genes are available and have already been used in other woody species, i.e.,

poplar, olive, cherry, kiwi, etc., and would be ready to be transferred into teak if it would have an efficient regeneration system. Several other genes will have to be characterized and isolated with their own promoters from several woody plants, including teak.

3.1.1 Reduction in the reproductive cycle of tree

The long reproductive cycle of teak is one of the main limitations of plant breeding. Identifying and manipulating some traits involved in flowering could be possible for the induction flowering phase in teak in order to reduce its reproductive cycle. Some *Arabidopsis* homeotic genes induce early flowering when expressed ectopically in transgenic plants since they are involved in flower initiation (Mizukami and Ma, 1992). Mandel and Yonofsky (1995) demonstrated that early flowering can be induced when homeotic genes (*API* and *LFY*) are expressed in transgenic plants. Expression of *API* (APETALA1) and *LFY* (LEAFY) genes was shown in transgenic citrus plants to produce fertile flowers and fruits as early as the first year through a mechanism involving an appreciable shortening of their juvenile phase (Peña *et al.*, 2001). The *LFY* gene was expressed in transgenic aspen and was able to produce flowers after some months of vegetative growth, in which flowering is usually observed after 8–20 years (Weigel and Nilsson, 1995). This approach could be extended to teak opening up the possibility of a reduction in generation time for accelerating the evaluation of mature agronomic traits, early fruit production, loss due to juvenile diseases, and probably also the anticipation of the wood cutting time.

3.1.2 Yield increase and wood quality

Alterations in the growth pattern and wood properties can be achieved as a consequence of the modification in tree architecture. The main purpose of genetic improvement is the increase of yield. Among several ways for achieving this goal, there is one that takes into account improvement of photosynthetic efficiency in plants. Plant architecture modification is a commonly used strategy to allow plants to capture more sunlight. The

ability of a single plant to adapt developmental plasticity of canopy confers high vigor under particular surrounding light quality environments (Schmitt *et al.*, 2003). Shade avoidance response is considered as the plant's reaction to light stress conditions that interfere with the normal development (Franklin and Whitelam, 2004). Light quality is altered by natural heavy canopy and by the light reflected by neighboring plants, influencing the plant development (Gilbert *et al.*, 2001). Perception of ambient light qualities enriched in far-red light occurs through a well-characterized phytochrome photoreceptor system that leads to plasticity adaptation (Mathews, 2005). The regulation of different light qualities can modulate development, apical dominance, and bud release in plants (Muleo *et al.*, 2001). Taking into account all these light quality effects, an overexpression of phytochrome B gene (*Phy B*) from *Arabidopsis thaliana*, in transgenic teak plants could improve architecture and energy capture that could be translated into greater harvestable yield. Another way to modify tree architecture with a probable improvement of wood quality is the overexpression of *GA-20* oxidase gene from *Arabidopsis* as proved in hybrid aspen that was altered in its phenotype growing faster in height and girth, with larger leaves and xylem fibers and increment of the biomass (Eriksson *et al.*, 2000). Another potential molecular approach that could be applied in teak is the enhancement of the growth through higher efficiency of nitrogen assimilation as shown in *Populus* by Gallardo *et al.* (1999), who developed a molecular approach to increase glutamine production in transgenic poplar by overexpressing a conifer *GS* (glutamine synthetase) gene. Expression of the pine *GS1* gene was also associated with an increase in chlorophyll content in leaves of transformed trees.

3.1.3 Stress tolerance

Modification of polyamine levels by overproduction of arginine decarboxylase (*ADC*) or ornithine decarboxylase (*ODC*) enzymes could lead to significant changes in plant development in teak. Enhanced growth under saline stress conditions was observed in transgenic rice plants (Roy and Wu, 2001). It suggests that enhanced

polyamine production as a result of overexpression of *ADC* may enhance plant development and stress tolerance. Regulation of putrescine catabolism was reported in transformed *ODC* poplar cells where the transgenic cells produced three- to fourfold higher amounts of putrescine than the nontransgenic cells (Bhatnagar *et al.*, 2002). Besides enhancement of stress tolerance, this approach could improve other important functions in plant development; for instance, the increase of rooting, since it is known that stimulation of root growth can be obtained by means of exogenous application of putrescine as reported in *in vitro* rooting of teak (Mendoza-de Gyves *et al.*, 2007) and in other woody species (Rugini and Wang, 1986; Rugini *et al.*, 1993; Hausman *et al.*, 1997).

3.1.4 Resistance to insects and diseases

The attack by pests to teak plants results in a significant loss caused by defoliation. It leads to the reduction of growth and in the long run affects the tree shape, yield, and wood quality. The incorporation of *Bt* pest resistance into teak genome may be a powerful defense for teak against lepidopteran insect attack. The first step toward this purpose has been taken. Norwati *et al.* (2003) reported transformation of teak tissues using the *CryIA(b)* gene coding for a *B. thuringiensis* toxin, even if it was just a preliminary experiment since the *CryIA* gene was applied along with the *GUS* gene in order to assess the efficiency of transformation method used by expressing β -glucuronidase activity in transformed tissues. Previously, some studies about the toxic effectiveness of commercial *Bt* formulations and some strains of *B. thuringiensis* had been evaluated against the teak skeletonizer, *P. damastesalis* (Intachat *et al.*, 2000). The *Bt* toxin acts well against this terrible teak enemy, and its genetic manipulation is feasible.

Since seedlings of teak in nurseries are susceptible to collar rot disease caused by *R. solani* (Ramesh, 2000), there is possibility of the use of basic chitinase-encoding gene, isolated from rice, in transgenic teak plants to express resistance to *R. solani* as reported in transgenic *Stylosanthes guianensis* plants (Kelemu *et al.*, 2005). Fungal diseases (*Nectria* spp. and *Fusarium*

spp., etc.) can cause considerable damage to teak roots (Arguedas and Quirós, 1997). An alternative to the use of expensive fungicides, transferring antimicrobial peptides (*AMP*) genes into teak, could be employed to induce fungal resistance in future. The feasibility of fungal disease resistance has been shown in transgenic apple plants by expression of *AMP* genes in *in vitro* fungal inhibition assays (Broothaerts *et al.*, 2000).

3.1.5 Qualities from teak

There are a number of potential utilities that teak can provide to other species. Biotechnology can be used to produce plants carrying the desired traits. Molecular marker-based strategies can accelerate the process of identification and incorporation of genes into other species. Teak is a unique species that could contribute an enormous number of traits including resistance to pests and diseases, better wood quality, and production of important secondary metabolites to other plants, even in annual ones. For example, the identification and isolation of the genes responsible of some determined function or quality could be useful for improvement of other trees and crops. Some of them include the ability to overcome water stress problems (Rajendrudu and Naidu, 1997); good wood properties giving excellent characteristics of durability and resistance, helping to withstand waterlogging (Brennan and Radomiljac, 1998); and also the production of several useful extractive compounds with antibacterial activity such as triterpene acid, against *E. coli* and *B. subtilis* (Marwani *et al.*, 1997); tectoquinone, a bioactive compound for the inhibition of *C. puteana*, a strong wood destroying fungus (Haupt *et al.*, 2003); Juglone extract from the bark, which inhibits certain enzymes needed for metabolic function of some microorganisms (Neamatallah *et al.*, 2005). Other important extractive compounds to be used in different fields could be lapachol, which gives the wood resistance to termites (Schmalle and Hausen, 1984); the Betulin aldehyde from the bark that can be used as an antitumour agent (Pathak *et al.*, 1988); anthraquinoid compound produced in leaves, which is used for dyeing silk, cotton, and wool (Vankar *et al.*, 2003; Mahale *et al.*, 2004).

3.2 Addressing Risks and Concerns: Damage to Human and Environment

The potential negative impact on biodiversity and environment is one of the main concerns associated with transgenic plants. One of the main concerns is the risk of transferring introduced genes from genetically engineered trees to wild populations through cross-pollination. Gene flow from domesticated transgenic plants can have potentially harmful consequences of evolution, increasing weeds and likelihood of extinction of wild relatives (Ellstrand, 2001). If the transgenic plant trait confers a selective advantage in natural environments, gene flow may affect biodiversity and can impact the entire ecosystem. Studies of gene transfer from conventional and transgenic plants to wild relatives and other plants in the ecosystem have so far concentrated on species of economic importance such as wheat, maize, and barley. The possible gene transfer from putative transgenic teak plants to wild relatives is rather impossible since this species possesses neither a high reproductive potential nor short regeneration time as may occur with annual crops. The absence of data, particularly for forest species, establishes the need to carefully monitor any possible effects of novel transgenic plants in the field (Hokanson *et al.*, 1997). As regards the probable direct impact of transgene products on the environment, it should be evaluated according to their potential to become environmental hazards. It is necessary to consider the kind of toxin produced in the plant. Products used to kill pests should be tested for nontarget effects. An attempt to transform teak has been carried out using a gene that produces a *Bt* toxin. However, the presence of the toxin in active form is not necessarily an environmental hazard because *Bt* toxins affect only select groups of insects, and must be ingested (James *et al.*, 1998).

The use of commercial, transgenic crops expressing *Bt* toxins has been increasing during the last few years because of their advantages with respect to the traditional chemical insecticides. However, the transgenic technique has potential for dealing with the development of insect resistance to the toxin. In crops with varying degrees of susceptibility to *Bt*, there is concern regarding the suboptimal production of toxin, resulting in reduced efficacy and increased risk of *Bt* resistance. If an insect develops resistance to

one *Bt* protein, it also develops resistance to other *Bt* proteins. This is called cross-resistance. The alterations of coding regions to avoid resistance require an understanding of how the insecticidal proteins interact with the insect on a biochemical level (Wolfenbarger and Phifer, 2000; Scriber, 2001). Kota *et al.* (1999) have delineated an approach for overcoming *Bt* resistance in insects that combines an overexpression of *Bt* protein (*Cry2Aa2*) with tissue specificity. They have also proposed the introduction of the *Bt* gene into the chloroplast, rather than into the nuclear genome because the chloroplast genome is maternally inherited, avoiding the transgene spread via pollen to nontarget plants.

3.2.1 Antibiotic resistance genes

Antibiotic resistance genes were also used in transformation experiments in teak. Some experts think that there would be little concern with the use of antibiotic resistance genes as selectable markers. Hygromycin may have important veterinary uses and, therefore, its use should be carefully evaluated in those crops that have animal feed applications. The fact that an antibiotic resistance gene is under a eukaryotic promoter in the plant is frequently cited as a barrier since the eukaryotic promoter would not be able to direct its expression in the micro-organism. However, the experts noted that rearrangements, especially under selective pressure, could easily bring a prokaryotic promoter in front of the gene leading to expression. In genetic transformation of forest trees, there have not been found so many critical opinions about the risk of human health damage compared with those crops destined for food. However, transgenic forest trees can present possible risks to the environment whichever is the kind of gene used.

3.2.2 Disruption of current cropping schemes and of traditional practices and economies in less developed countries

Transgenic trees if cultivated in Asian regions where native trees are established could have a potential behavior similar to that of invasive species. In some Asian countries, the natural

forests are still important for teak production and a large part of the economy depends on that. There is a potential risk in eliminating indigenous tree populations, thus seriously disturbing ecosystems. Transgenic trees will likely be patented, making an already bad situation worse, leading toward a small group of large timber corporations controlling the industry. Another negative effect could include a reduced market in which the participation of small producers and growers with nontransgenic stock could not be possible. In other tropical countries like Central Americans or Africans, it probably would not affect their traditional practices. For instance, in Costa Rica there are strong governmental incentives to promote the establishment of commercial tree plantations (Sage and Quiros, 2001). They accept any innovation to adopt in their programs without being concerned about natural teak plantations. Nevertheless, a controversy has been created concerning the Netherlands owned company, *Flor y Fauna*, involved in establishing large teak plantations in Costa Rica (Pandey and Brown, 2000).

3.3 Expected Technologies

3.3.1 Improved transformation efficiency

An inefficient system for insertion of genes in large numbers in tree species is the first obstacle to continue on the route toward the advanced improvement. First of all, it is necessary to overcome the main problems existing for genetic manipulation of teak. As mentioned above, the bottleneck is the high recalcitrance that teak presents to be regenerated. This limitation reduces the capacity of the whole transformation process. Some achievements have been made: *Agrobacterium* susceptibility in teak was tested; the first experiments with transient expression were carried out successfully; identification of genetic markers has been initiated with some progress. Nevertheless, the low capacity to regenerate from somatic tissues has obstructed the continuity in transgenic experiments. It is expected to overcome this barrier in order to improve the transformation efficiency; may be adopting and perfecting the transformation procedure using *meristematic bulk* proposed for *Vitis vinifera* by Mezzetti *et al.* (2002).

3.3.2 Alternative to antibiotic resistance genes

According to EU directive (90/220/EEC) on deliberate release of genetically manipulated organisms (GMO) into the environment, new transgenic plants containing antibiotic resistance genes will not be approved to market after 2004 and for experimental field release after 2008 in Europe (Haslberger, 2000). As in other species, transformation experiments on teak are being carried out with the only purpose of studying the plants since the transgenic plants that are modified using an antibiotic resistance gene as marker cannot be commercialized. This is another obstacle to overcome. The community is afraid of potential risks associated with the use of antibiotic resistance genes, recommending the use of alternatives to these genes. Particular consideration is given to those that contain antibiotic resistance genes for therapeutic antibiotics. Therefore, the replacement of antibiotic resistance genes with alternative selectable markers is required for the future of genetic-modified plants.

3.3.3 More specific promoters

Genes are able to turn on or off depending on different factors such as places and times during the life cycle of an organism. This gene regulation involves molecular signals that act on DNA sequences encoding protein products. Specific promoters are necessary in order to minimize the concerns for environmental biosafety from the use of genetically engineered trees. It is important to limit the expression of the introduced gene in the specific tissues. For example, in the case of searching for a metabolic approach for producing value-added hardwood products, the identification of trunk wood-specific genes and subsequently their promoter regions becomes necessary. Tissue-specific promoters should be used that operate in particular tissues and at certain developmental stages of a plant. They could also be classified as inducible promoters since they may be induced by endogenous and exogenous factors. The promoter region of the genes will then be used to drive the genes of interest, expressing them only in the specific tissue.

3.3.4 Transfer of multigene DNA fragments

Introduction of multiple transgenes and modifying more complex traits are frequently required for basic and applied studies. However, at present, multigene transformation is very difficult due to technical limitations of existing methods. Some attempts, with respect to this approach, are being made, including sexual crossing, retransformation, cotransformation, and the use of linked transgenes (Halpin *et al.*, 2001). However, due to the delay in transformation trials with a single gene in teak, the idea to modify complex traits in this species seems too remote.

3.4 Intellectual Property Rights, Public Perceptions, Industrial Perspectives, Political and Economic Consequences

Modern biotechnology participates in an important political controversy. Public perception in Europe is too negative against genetic engineering. It seems that institutions of the public sectors have not handled the information about GMO really well. The role of the mass media is more often subject to polemics rather than empirical analysis. There is much mistrust in the public mind, and people generally do not trust regulators. There is not much chance to explain to consumers that it is not only a multinational industry affair but a benefit for the entire world. Not all people pay attention to agricultural biotechnology and there are people who do not have requisite knowledge about it. Opinions of GMO are easily influenced. Approval increases when specific benefits of GMO are mentioned; however, some reactions to the technology depend on how they are called: for example, the term *biotechnology* suggests the most positive responses, while *genetic modification* is perceived most negatively (Bauer, 2005).

As regards political and economic consequences, the possible introduction of transgenic plantations in developing countries could have considerable risks leading to increased inequality of income and wealth. Affluent farmers are likely to obtain most of the benefits through early adoption of the technology. A few companies could concentrate on the biotechnology research leading to reduced competition and creating monopoly

or oligopoly markets. There is a necessity to constitute a strong antitrust legislation.
